We measure the full distribution of current fluctuations in a single-electron transistor with a controllable bistability. The conductance switches randomly between two levels due to the tunneling of single electrons in a separate single-electron box. The electrical fluctuations are detected over a wide range of time scales and excellent agreement with theoretical predictions is found. For long integration times, the distribution of the time-averaged current obeys the large-deviation principle. We formulate and verify a fluctuation relation for the bistable region of the current distribution.

DOI: 10.1103/PhysRevB.94.241407

Introduction. Nanoscale electronic conductors operated at low temperatures are versatile tools to test predictions from statistical mechanics [1–3]. The ability to detect single electrons in Coulomb-blockaded islands has in recent years paved the way for solid-state realizations of Maxwell’s demon [4,5], Szilárd’s engine [6], and the Landauer principle of information erasure, complementing experiments with colloidal particles [7–9]. Moreover, several fluctuation theorems have been experimentally verified in electronic systems, including observations of negative entropy production at finite times [10–14]. Bistable systems constitute another class of interesting phenomena in statistical physics [15]. Bistabilities can be found in many fields of science [16,17] and can, for example, be caused by external fluctuators or intrinsic nonlinearities. Bistabilities lead to flicker noise which can be detrimental to the controlled operation of solid-state qubits [18] and other nanodevices whose fluctuations we wish to minimize [19,20].

In this Rapid Communication, we realize a controllable bistability that causes current fluctuations in a nearby conductor. The tunneling of electrons in a single-electron box (SEB) makes the conductance switch between two levels in a nearly single-electron transistor (SET) whose current is monitored in real time. With this setup, we can accurately measure the distribution of current fluctuations in a bistable conductor, including the exponentially rare fluctuations in the tails, and we can test fundamental concepts from statistical physics as we modulate the bistability in a controlled manner.

Experimental setup. Figure 1(a) shows an SET which is capacitively coupled to an SEB. Both are composed of small normal-conducting islands coupled to superconducting leads via insulating tunneling barriers. Measurements are performed at around 0.1 K, well below the charging energy of both the SEB and the SET. The tunneling rates of the SEB are tuned to the kilohertz regime so that the tunneling of electrons on and off the SEB is separated by milliseconds. The tunneling rates in the SET are on the order of several hundred megahertz and the electrical current is in the range of picoamperes. The conductance of the SET is highly sensitive to the presence of individual electrons on the SEB. This can be used to detect the individual tunneling events in the SEB by monitoring the current in the SET [see Fig. 1(b)] [22–31]. Here, by contrast, we turn around these ideas and instead focus on the current fluctuations in the SET under the influence of the random tunneling events in the SEB [32].

FIG. 1. Experimental setup. (a) False-colored scanning electron micrograph of the SET (brown) and the SEB (blue). Both devices are fabricated by electron beam lithography and three-angle shadow evaporation [21]. The gate voltages $V_{g1}$ and $V_{g2}$ are used to control the tunneling rates. The bias voltage $V$ is applied across the SET and the current $I$ is measured. (b) The current in the SET switches between the two normalized values $\langle I_+ \rangle = 0$ and $\langle I_- \rangle = 1$ due to the tunneling of single electrons on and off the SEB. (c) Distribution of the time-integrated current $\langle I \rangle$ for the integration time $\tau = 180 \text{ ms}$, together with the tilted ellipse given by Eq. (4). The controllable rates for tunneling on and off the SEB are $\Gamma_+ = 72 \text{ Hz}$ and $\Gamma_- = 37 \text{ Hz}$. We measure the full distribution of current fluctuations in a single-electron transistor with a controllable bistability. The conductance switches randomly between two levels due to the tunneling of single electrons in a separate single-electron box. The electrical fluctuations are detected over a wide range of time scales and excellent agreement with theoretical predictions is found. For long integration times, the distribution of the time-averaged current obeys the large-deviation principle. We formulate and verify a fluctuation relation for the bistable region of the current distribution.

Time-averaged current. Our dynamical observable is the time-averaged current

$$I(\tau) = \frac{1}{\tau} \int_0^\tau dt I(t)$$

A general feature of stochastic processes is their time-averaged current $I(\tau)$, which is related to the current $I(t)$ by

$$\langle I \rangle = \frac{1}{\tau} \int_0^\tau dt I(t)$$

where $\tau$ is the integration time. The time-averaged current $I(\tau)$ is a measure of the average current over the time interval $[0, \tau]$. It is a fundamental quantity in the study of stochastic processes and provides insights into the dynamics of the system.
measured over the time interval \([t_0,t_0 + \tau]\). For stationary processes, the distribution of current fluctuations depends only on the length of the interval \(\tau\) and not on \(t_0\). The distribution is expected to exhibit general properties that should be observable in any bistable conductor. For example, it has been predicted [34] and verified in a related experiment [25] that the logarithm of the distribution at long times is always given by a tilted ellipse (see Fig. 1(c) and Refs. [35,36]). Besides, the crossover from short to long times (see Fig. 2) gives additional information about the bistable system (SEB). This information can be used for the detection and characterization of parasitic two-level fluctuators that may be present in the vicinity of a device, since the fluctuation statistics should be universal for all such two-level systems, as we will see.

**Measurements.** Figure 2(a) shows experimental results for the distribution of the time-averaged current. For short integration times, the distribution is bimodal with two distinct peaks corresponding to having either \(n = 0\) or \(n = 1\) electrons on the SEB. According to the central limit theorem, the fluctuations should become normal distributed with increasing integration time \(\tau\), having a variance that decreases as \(O(\tau^{-1/2})\). This expectation is confirmed by Fig. 2(a), showing how the distribution becomes increasingly peaked around the mean \(\langle I \rangle\).

This behavior is similar to the suppression of energy or particle fluctuations in the ensemble theories of statistical mechanics [37], here with the limit of long integration times playing the role of the thermodynamic limit. However, even as the distribution becomes increasingly peaked, rare fluctuations persist [38]. This can be visualized by using a logarithmic scale which emphasizes the rare fluctuations encoded in the tails of the distribution [Fig. 2(b)]. The rare fluctuations will be important when we below formulate and test a fluctuation theorem.

**Theory.** To better understand the fluctuations we develop a detailed theory of the distribution function \(P_\tau(I)\). The current fluctuates due to the random tunneling in the SEB and because of intrinsic noise in the SET itself. This we describe by the stochastic equation

\[
\dot{I}(\tau) = [1 - \mathcal{N}(\tau)](I_-) + \mathcal{N}(\tau)(I_+) + \xi(\tau),
\]

where the first two terms account for the random switching between the average currents \(\langle I_- \rangle\) and \(\langle I_+ \rangle\) and we have defined the time-averaged electron number \(\mathcal{N}(\tau) = \int_{t_0}^{t_0 + \tau} dt \delta(t)/\tau\) on the SEB with \(n = 0.1\) [35]. The time-averaged noise \(\langle \xi(\tau) \rangle\) describes the intrinsic fluctuations around the mean values \(\langle I_- \rangle\) and \(\langle I_+ \rangle\), assumed here to be independent of \(n\). The distribution of current fluctuations \(P_\tau(I)\) is now determined by the fluctuations of \(\mathcal{N}(\tau)\) and the intrinsic noise \(\xi(\tau)\). Electrons tunnel on and off the SEB with the tunneling rates \(\Gamma_+\) and \(\Gamma_-\), changing \(n\) from 0 to 1 and vice versa, respectively. The distribution \(P_\tau(\mathcal{N})\) then becomes [39]

\[
P_\tau(\mathcal{N}) = \frac{e^{-\mathcal{N}(\tau)\delta(1 - \mathcal{N})} \Gamma_+ + \Gamma_-}{\Gamma_+ + \Gamma_-} \left\{ \mathcal{N}(\Gamma_+ \delta(1 - \mathcal{N}) + \Gamma_- \delta(1 - \mathcal{N}) + 2\tau \Gamma_+ \Gamma_- \Pi(\mathcal{N}) \left[ I_0(x) + \tau(\mathcal{N}(1 - \mathcal{N}) + \mathcal{N} \Gamma_+ \mathcal{N} \left[ I_0(x) + \tau(\mathcal{N}(1 - \mathcal{N}) + \mathcal{N} \Gamma_+ \mathcal{N} \left[ \frac{I(x)}{x} \right] \right) \right] \right] \right\}.
\]
ing to $P_{\tau}(I)$ being bimodal with distinct peaks centered around the two average currents $\langle I_- \rangle$ and $\langle I_+ \rangle$. With increasing integration time, the distribution eventually takes on the large-deviation form $P_{\tau}(N) \propto e^{G(N)/\tau}$ with the rate function $G(N) = -\left[\sqrt{\Gamma_+ (1-N)} - \sqrt{\Gamma_- (N-1)}\right]^2/\langle I_+ \rangle - \langle I_- \rangle$ following directly from Eq. (3). Moreover, the long-time limit of the distribution describes the low-frequency current fluctuations which should be dominated by the slow switching process. We can then ignore $\bar{\xi}(\tau)$ in Eq. (2) such that the distribution becomes [34]

$$
\ln P_{\tau}(I) \approx -\left[\sqrt{\Gamma_+(I_+ - \bar{I})} - \sqrt{\Gamma_-(I_- - \bar{I})}\right]^2/\langle I_+ \rangle - \langle I_- \rangle. \quad (4)
$$

The rate function on the right-hand side characterizes the non-Gaussian fluctuations of the current beyond what is described by the central limit theorem [38]. Importantly, the rate function is independent of the integration time and it captures the exponential decay of the probabilities to observe rare fluctuations. Geometrically, the rate function describes the upper part of a tilted ellipse, delimited by the currents $\langle I_+ \rangle$ and $\langle I_- \rangle$ [25,34–36]. The tilt is given by the ratio of the controllable tunneling rates $\Gamma_+$ and $\Gamma_-$ and its width is governed by their product (see the prefactor in the parameter $x$). The tilted ellipse agrees well with the experimental results in the bistable range $\langle I_- \rangle \leq \bar{I} \leq \langle I_+ \rangle$, as seen in Fig. 1(c). The extreme tails of the distribution are determined by the intrinsic fluctuations around $\langle I_- \rangle$ and $\langle I_+ \rangle$ which are not included in Eq. (4).

By adjusting the tunneling rates we can control the shape and the tilt of the ellipse, as illustrated in Fig. 3(a). For $\Gamma_- \gg \Gamma_+$, the ellipse is strongly tilted to one side and the distribution is mostly centered around $\langle I_- \rangle$. As the ratio of the rates is changed, the ellipse becomes tilted to the other side and the distribution gets centered around $\langle I_+ \rangle$. The average $\bar{I}$ is given by the value of $\bar{I}$ where the distribution is maximal. This value changes from $\langle I_- \rangle$ to $\langle I_+ \rangle$ as we tilt the ellipse. The abruptness of the change is determined by the width of the ellipse.

**Universal semicircle.** To provide a unified description of the fluctuations we define the rescaled distribution

$$
G(I) \equiv \frac{1}{2\sqrt{\Gamma_+ \Gamma_-}} \left\{ \ln P_{\tau}(\bar{I}) + \Gamma_+ \Delta I_+ - \Gamma_- \Delta I_- \right\}/(\langle I_+ \rangle - \langle I_- \rangle), \quad (5)
$$

where the second term in the braces explicitly removes the tilt of the distribution and we have defined $\Delta I_{\pm} = \bar{I} - \langle I_{\pm} \rangle$. From Eq. (4), we then obtain the semicircle

$$
G^2(I) + \left(\frac{\bar{I} - \bar{I}}{\langle I_+ \rangle - \langle I_- \rangle}\right)^2 = 1, \quad (6)
$$

which should describe the fluctuations in any bistable conductor independently of the microscopic details. Here we have defined $\bar{I} = (\langle I_+ \rangle + \langle I_- \rangle)/2$. Figure 3(b) shows that our experimental data in Fig. 3(a) measured at long times indeed collapse onto this semicircle when rescaled according to Eq. (5). This property should hold for a variety of bistable systems from different fields of physics.

**Fluctuation relation.** Finally, we examine the symmetry properties of the fluctuations [41]. Equation (4) is suggestive of a fluctuation relation at long times reading

$$
\frac{1}{\Omega} \ln \left[ \frac{P_{\tau}(\bar{I} = \bar{I} + J)}{P_{\tau}(\bar{I} = \bar{I} - J)} \right] = \Omega J, \quad (7)
$$

where $\Omega = 2(\Gamma_+ - \Gamma_-)/(\langle I_+ \rangle - \langle I_- \rangle)$ controls the slope. This relation is reminiscent of the Gallavotti-Cohen fluctuation theorem [42,43], however, here the intensive entropy production is replaced by the departure $\bar{J}$ from the average $\bar{I}$ of the mean currents. Equation (7) should be valid in the bistable region of the distribution which is dominated by the random tunneling in the SEB. The excellent agreement between theory and experiment in Fig. 4 confirms the prediction. The fluctuation relation is expected to be valid for many different bistable systems and may be further tested in future experiments.

**Conclusions.** We have realized a controllable bistability in order to investigate the fundamental properties of current fluctuations in bistable conductors. These include the crossover from short-time to long-time statistics, the large-deviation principle, and the fluctuation relation in the long-time limit.
Our results have an immediate application for the detection and characterization of spurious two-level fluctuators which appear in many solid-state devices, since their fluctuations are universal and independent of the microscopic details. We have formulated and verified universal properties including a fluctuation relation for bistable conductors. Our work establishes several analogies between bistable conductors and concepts from statistical mechanics and it offers perspectives for further experiments on statistical physics with electronic conductors.
