The electrooxidation-induced structural changes of gold di-superatomic molecules: Au\textsubscript{23} vs. Au\textsubscript{25}\textsuperscript{†}

Shota Matsuo, Seiji Yamazoe, Jing-Qiang Goh, Jaakko Akola and Tatsuya Tsukuda*

The gold cluster compounds Au\textsubscript{38}(SC\textsubscript{2}H\textsubscript{4}Ph)\textsubscript{24} and [Au\textsubscript{25}(PPh\textsubscript{3})\textsubscript{10}(SC\textsubscript{2}H\textsubscript{4}Ph)\textsubscript{5}Cl\textsubscript{2}]\textsuperscript{2+} are known to possess bi-icosahedral Au\textsubscript{23} and Au\textsubscript{25} cores, respectively, inside their ligand shells. These Au cores can be viewed as quasi-molecules composed of two Au\textsubscript{13} superatoms sharing three and one Au\textsuperscript{+} atoms, respectively. In the present work, we studied the structural changes of these gold di-superatomic molecules upon electrooxidation via spectroelectrochemical techniques, X-ray absorption fine structure analysis, and density functional theory calculations. The Au\textsubscript{23} core was electrochemically stable, but the Au\textsubscript{25} core underwent irreversible structural change. This marked difference in the stability of the oxidized states is ascribed to differences in the bonding scheme of Au\textsubscript{13} units and/or the bonding nature of the protecting ligands.

Introduction

The Au\textsubscript{13} icosahedron is a ubiquitous structural motif that can be found in a variety of ligand-protected gold clusters, such as [Au\textsubscript{13}(PMe\textsubscript{2}Ph)\textsubscript{10}Cl\textsubscript{2}]\textsuperscript{3+}, \[\text{Au}_{25}(\text{SC}_{2}\text{H}_{4}\text{Ph})_{18}\], \[\text{Au}_{13}(\text{PPh}_{3}C_{2}\text{H}_{4}\text{PPh}_{3})_{5}\text{Cl}_{2}]\textsuperscript{2+}, \[\text{Au}_{13}(\text{PPh}_{2}C_{2}\text{H}_{4}PPh_{2})_{5}\text{Cl}_{2}]\textsuperscript{2+}, and \[\text{Au}_{13}(\text{PPh}_{2}C_{2}\text{H}_{4}PPh_{2})_{5}(C_{2}\text{CPh})_{2}]\textsuperscript{3+}. All of these Au\textsubscript{13} cores formally accommodate eight valence electrons with a closed (1S)\textsubscript{2}(1P)\textsubscript{6} electronic configuration, where S and P represent orbitals with angular momentum values of 0 and 1, respectively (Scheme 1).\textsuperscript{7,8}

\[\text{Au}_{13}\textsuperscript{5+}(8e)\] can be viewed as a dimer of halogen-like Au\textsubscript{13}\textsuperscript{6+}(7e) superatoms formed by sharing three Au\textsuperscript{+} atoms (Scheme 1a):\textsuperscript{9}

\[
\text{Au}_{23}\textsuperscript{9+}(14e) = 2 \times \text{Au}_{13}\textsuperscript{6+}(7e) - 3\text{Au}^+ (1)
\]

The electronic configuration of Au\textsubscript{13}\textsuperscript{9+}(14e) may be described as (1\textsigma\textsuperscript{2})(1\textsigma\textsuperscript{*})\textsuperscript{2}(1\textpi\textsuperscript{4})(2\textsigma\textsuperscript{2})(1\textpi\textsuperscript{*})\textsuperscript{4}. The 1\textsigma\textsuperscript{0} and 1\textsigma\textsuperscript{*} orbitals are constructed from the 1S superatomic orbitals of Au\textsubscript{13}\textsuperscript{6+}(7e), and the 1\textpi\textsuperscript{0} and 1\textpi\textsuperscript{*} orbitals are constructed from the 1P superatomic orbitals of Au\textsubscript{13}\textsuperscript{6+}(7e).

Scheme 1 Schematic representation of the bonding scheme for (a) Au\textsubscript{23}\textsuperscript{9+}(14e) and (b) Au\textsubscript{25}\textsuperscript{9+}(16e) from their superatomic units (ref. 18 and 19). The energy scales are arbitrary and the energy splitting of superatomic orbitals (ref. 20 and 21) is ignored. Optical transitions A, B, and C correspond to the peaks in the optical spectrum (Fig. 1a).

The Au\textsubscript{13} core serves as the building unit for a new class of quasi-molecules known as superatomic molecules\textsuperscript{9,10} in a manner analogous to the formation of molecules from atoms. To date, two different bonding modes have been revealed by single-crystal X-ray crystallographic studies. One is a face-sharing mode found in the Au\textsubscript{23}\textsuperscript{9+}(14e) core of Au\textsubscript{38}(SC\textsubscript{2}H\textsubscript{4}Ph)\textsubscript{24}.\textsuperscript{11} The other is a vertex-sharing mode found in the Au\textsubscript{25}\textsuperscript{9+}(16e), Au\textsubscript{37}\textsuperscript{13+}(24e), and Au\textsubscript{60}\textsuperscript{20+}(40e) cores of \[\text{Au}_{25}(\text{PPh}_{3})_{10}(\text{SC}_{2}\text{H}_{4}\text{Ph})_{5}\text{Cl}_{2}]\textsuperscript{2+}, \[\text{Au}_{37}(\text{PPh}_{3})_{10}(\text{SC}_{2}\text{H}_{4}\text{Ph})_{10}\text{Cl}_{2}]\textsuperscript{+}, and \[\text{Au}_{60}\text{Se}_{2}(\text{PPh}_{3})_{10}(\text{SeR}_{0})_{15}\text{Cl}_{2}]\textsuperscript{+}, respectively. A recent computational study suggests that the Au\textsubscript{23}\textsuperscript{9+} core ...
whereas the 1π, 2σ, and 1π* orbitals result from the 1P superatomic orbitals of Au_{13}^{9+}(7e). This super valence bond model can also be applied to bonding in the vertex-sharing Au_{25}^{9+}, which may be considered as a dimer generated by rare gas-like Au_{13}^{5+}(8e) superatoms sharing an Au⁺ atom (Scheme 1b):12,15-17

\[ \text{Au}_{25}^{9+}(16e) = 2 \times \text{Au}_{13}^{5+}(8e) - \text{Au}^+. \]  

The formal bond orders in Au_{23}^{9+} and Au_{25}^{9+} can be calculated to be one and zero, respectively.

In terms of the bonding scheme, the Au_{23}^{9+}(14e) and Au_{25}^{9+}(16e) cores correspond to an F_{2} molecule and a van der Waals dimer of Ne, respectively. These di-superatomic molecules, thus, provide an interesting opportunity to study similarities and differences of the fundamental properties between conventional molecules and superatomic molecules. This study aims to compare the structural changes of superatomic molecules induced by electrooxidation with those of conventional molecules by ionization. In the case of molecules, the bond distance is the unique structure parameter that can be changed. For example, the F–F bond of F_{2} is shortened from 1.44 to 1.33 Å upon ionization owing to the removal of an electron from the highest occupied molecular orbital (HOMO) of anti-bonding nature.22 The internuclear distance of Ne_{2} is significantly reduced from 3.09 to 1.7 Å upon ionization owing to the charge-resonance stabilization in Ne_{2}.23 In the case of superatomic molecules, the structural change of superatomic units themselves may be induced in addition to the elongation/reduction of their distance. In the present study, we investigated how the geometric structures of the Au_{23}^{9+} and Au_{25}^{9+} cores are altered upon electro-oxidation using spectroelectrochemical methods;24 X-ray absorption fine structure (XAFS) analysis and density functional theory (DFT) calculations.

**Experimental and computational methods**

**Synthesis of samples**

All of the chemicals used in this study were commercially available. Samples of Au_{38(SC_{2}H_{4}Ph)_{3}2} (1) and [Au_{25(PPh_{3})_{10}(SC_{2}H_{4}Ph)Cl_{2}]}^{2+} (2) were synthesized according to literature procedures, but with slight modifications.12,15,26 The details of the syntheses are described in the ESL. Successful synthesis of both compounds was confirmed by matrix-assisted laser desorption ionization (MALDI) mass spectrometry and optical absorption spectroscopy.

**Electrochemical measurements**

Cyclic voltammetry (CV) and differential pulse voltammetry (DPV) of 1 and 2 were performed using an electrochemical analyzer (BAS, ALS720B) at room temperature under an Ar atmosphere. The electrolyte solution used for these measurements was 0.1 M tetrabutylammonium hexafluorophosphate (NBu_{4}PF_{6}) in 1,2-dichloroethane (DCE) purged with Ar. The working, reference, and counter electrodes were a 1 mm glassy carbon disk, Ag/AgNO_{3} (−0.21 V vs. Fc/Fc+), and a Pt wire, respectively. The potential scan was initiated at open circuit potential (0.01 and −0.27 V for 1 and 2, respectively) in the negative direction.

The optical absorption spectra of 1 and 2 in the UV-vis-NIR region were recorded under electrochemical redox conditions. These spectrophotometric measurements were conducted in a DCE solution containing 0.1 M NBu_{4}PF_{6} that was purged with Ar prior to measurements using an electrochemical analyzer (BAS, ALS720B) and two spectrophotometers (Jasco, V-670 for 1 and Agilent, Agilent 8453 for 2). A quartz cell (1 mm width) was used for spectrophotometry. The working, reference, and counter electrodes were an optically transparent Pt mesh electrode, an Ag/AgNO_{3} electrode, and a Pt wire electrode, respectively. The Pt mesh electrode was set in the light path of the spectroelectrochemical cell.

**Bulk electrolysis**

The bulk electrolysis of 2 was carried out in a spectrophotometric 10 mm quartz cell (HX-701Y, Hokuto Denko) with an electrochemical analyzer (BAS, ALS720B). The working, reference, and counter electrodes were a Pt mesh electrode, an Ag/AgNO_{3} electrode, and a Pt coil electrode, respectively. The electrolysis was conducted in a DCE solution containing 0.1 M NBu_{4}PF_{6} which was purged with Ar prior to measurements. The completion of the bulk electrolysis was established by optical absorption spectroscopy.

**XAFS spectroscopy**

Au L_{3}-edge XAFS measurements were performed on the BL01B1 beamline at the SPring-8 facility of the Japan Synchrotron Radiation Institute (proposal nos. 2012B1986, 2014B1430, and 2014A1680). A Si(311) two-crystal monochromator was used for the incident beam and all spectra were recorded in transmission mode using ion chambers as the I_{0} and I detectors. Samples of 2 diluted with boron nitride and 2 electrolyzed and diluted with NBu_{4}PF_{6} were placed in the cryostat for measurements at 8 or 10 K. Energy scale was calibrated using Cu foil and data analysis was carried out employing the REX2000 Ver. 2.5.92 software package (Rigaku Co.). The k^{2}-weighted χ spectra in the k range of 3.0–16.0 Å⁻¹ were Fourier-transformed (FT) into r-space. The curve fitting analysis was performed for Au–S (P, Cl) and Au–Au bonds over the r range of 1.5–3.2 Å. In the curve fitting analysis, the phase shifts and back-scattering amplitude functions for the Au–S and Au–Au bonds were extracted from Au_{8}S (ICSD#78718) and Au metal (ICSD#44362), respectively, using the FEFF8 program.27 The phase shifts and back-scattering amplitude functions of Au–S were used for those of Au–P and Au–Cl because the electron densities of P and Cl atoms are close to that of S atom.

**Transmission electron microscopy**

Transmission electron microscopy (TEM) images were recorded by using a Hitachi HF-2000 microscope operated at 200 kV. A dispersion of the electrooxidized sample of 2 was dropped onto a carbon-coated copper grid. The sample grid was dried at room temperature in air.

**Computational methods**

The GPAW software,28 a projector-augmented wave (PAW) and real-space grid DFT package, was employed to inspect the redox
behavior of 1 and 2. Structural optimizations were performed in the gas phase environment with consideration of the full ligands, until the residual forces acting on the atoms reached 0.05 eV Å⁻¹ or below. The spin-polarized DFT simulations were performed with a real-space grid spacing of 0.2 Å and included the scalar relativistic effect for PAW setups. Linear response time-dependent DFT based on Casida’s formulation was employed to analyze the optical absorption spectra of 2⁺ and 3⁺. All the calculations in this work adopted the generalized gradient-corrected exchange-correlation functional developed by Perdew, Burke and Ernzerhof (PBE).²⁰

Results and discussion

Redox behavior of Au₃₈(SC₂H₄Ph)₂₄

The successful synthesis of Au₃₈(SC₂H₄Ph)₂₄ (1⁰) was confirmed by MALDI mass spectrometry (Fig. S1, ESI†). An intense peak at m/z = 1.078 × 10⁴ was assigned to intact Au₃₈(SC₂H₄Ph)₂₄, whereas a smaller peak at m/z = 9.33 × 10³ was attributed to a fragment with the formula Au₃₈(SC₂H₄Ph)₉S.²⁵ The optical absorption spectrum of 1⁰ (Fig. 1a) shows distinct peaks at 1.18 (peak A), 1.65 (peak B), 1.97 (peak C), 2.39, and 2.57 eV, in agreement with previously reported data.³¹ The peaks A, B and C have been theoretically assigned to the electronic transitions HOMO(1π*) → LUMO(2π*), HOMO−1(2σ*) → LUMO+1(2σ*), and HOMO(1π*) → LUMO+3, respectively (Scheme 1a).¹⁸

Fig. 1b shows the CV curves of 1⁰ recorded at different scan rates; an arrow indicates the open circuit potential. These plots exhibit two pairs of redox peaks for the 0+/1 and +1/+2 couples at the same voltages, regardless of the scan rates. The peak-to-peak separations of the two couples are 58 and 61 mV, respectively, at a scan rate of 100 mV s⁻¹. This reversible behavior indicates that 1⁰ and its oxidized forms 1¹⁺ and 1²⁺ are stable in the electrolyte solution. According to a previously reported theoretical study,¹⁸ the increased absorbance at 1.8 eV can be attributed to an optical transition to the HOMO(1π*) orbital, in which one or more holes are created by oxidation.

Fig. 2b shows the spectra obtained by subtracting the spectrum of 1⁰ from those of 1¹⁺ and 1²⁺. The peak positions evidently did not change upon oxidation, indicating that the energy levels of the superatomic orbitals of 1 do not change regardless of the charge state. Given that the electronic structures of small clusters are sensitive to slight difference in the geometric structure, this result indicates that the geometric structure of 1 is not changed appreciably by the redox reactions. Namely, the bond length between the Au₁₃ units within 1 was not changed even after the formal bond order is increased from 1 to 2. This behavior is in sharp contrast to that of F₂, a molecular analogue of Au₂₃⁹⁺, since it is known that the F–F bond length in F₂ (1.33 Å) is shorter than that in F₂⁺ (1.44 Å).²² The negligible structural change of Au₂₃⁹⁺,
even after 2-electron oxidation, thus demonstrates the structural rigidity of the face-sharing bi-icosahedral Au$_{13}$.

Furthermore, the DFT structural optimizations of 1$^0$ and 1$^{2+}$ support this finding showing that the bond distances of core atoms do not change significantly at different charge states (Fig. S3 and Table S1, ESI†). One of the HOMO(1π$^*$) orbitals in 1$^0$ is promoted to the LUMO orbital in 1$^{2+}$, but the HOMO orbitals of these structures still retain the same symmetry of 1π$^*$ (Fig. S4, ESI†). Hence, there is no distinctive structural effect induced by the electronic factor. The rigidity of Au$_{13}$ may partly arise from the protection by the rigid Au–SR oligomers with different lengths: especially three −SR–Au–SR− “staples” bridge across the waist of two Au$_{13}$ icosahedra.\cite{35}

**Redox behavior of [Au$_{25}$(PPh$_3$)$_{10}$(SC$_2$H$_4$Ph)$_5$Cl$_2$]$^{2+}$**

The synthesis of [Au$_{25}$(PPh$_3$)$_{10}$(SC$_2$H$_4$Ph)$_5$Cl$_2$]$^{2+}$ was confirmed by optical spectroscopy (Fig. 3a). The spectrum shows distinct peaks at 1.84, 2.98, 3.30, and 3.76 eV, which reproduces the reported data.\cite{12,36} The CV curves of 2$^{2+}$ shown in Fig. 3b exhibit irreversible waves in both the oxidative and reductive potential ranges. This result indicates that cluster 2$^{2+}$ is unstable upon one-electron oxidation.

Fig. 4a presents the optical absorption spectra obtained during one-electron oxidation of 2$^{2+}$ at 0.60 V. The spectral profile changes with time while exhibiting three isosbestic points, as indicated by arrows. The peak at 1.84 eV drops in intensity and the optical gap is reduced during the electro-oxidation reactions. This result implies that the electrooxidation of 2$^{2+}$ yielded a certain product having less structured absorption spectrum than 2$^{2+}$.

In order to gain insight into the electronic structures of the one-electron oxidation product, we attempted to extract its optical spectrum by assuming that 2$^{2+}$ is converted to a single species upon electrooxidation. Namely, we assume that the spectra in Fig. 4a represent a linear combination of the spectra of unoxidized 2$^{2+}$ and the oxidation product. Because the population of unoxidized 2$^{2+}$ at a certain time is unknown, we further assume that the oxidation product does not have sharp peaks at the same position with those of 2$^{2+}$. The optical spectra of the oxidation product extracted based on these assumptions are shown in Fig. 4b. Although there is an ambiguity in the spectral profile depending on the assumed concentration of unoxidized 2$^{2+}$, we can conclude that the oxidation product is less structured as compared to 2$^{2+}$ and optical onset is shifted to lower energy.

DFT calculations were carried out to study the geometric structure and optical properties of the one-electron oxidation product. Structural optimization of 2$^{3+}$ starting from vertex-sharing biicosahedral cores with eclipsed and staggered configurations (Fig. S5, ESI†) both yielded the eclipsed motif, which is similar to that of 2$^{2+}$ (Fig. 5a). The optimization results do not suggest that a staggered (twisted bi-icosahedral core)\cite{37} configuration is preferred for 2$^{3+}$, upon oxidation of 2$^{2+}$. Since the HOMO of 2$^{2+}$ has anti-bonding nature according to the previous theoretical calculations (Scheme 1b),\cite{15,17} one would expect that the distance between the two Au$_{13}$ units to become smaller upon oxidation. In contrast to the prediction from Scheme 1b, the distance between the two Au$_{13}$ units is slightly increased upon oxidation: the average distance between the nearest neighboring Au atoms between the Au$_{13}$ units are 3.23 ± 0.018 and 3.27 ± 0.015 Å for 2$^{2+}$ and 2$^{3+}$, respectively (Fig. 5a). This unexpected trend is due to the fact that the HOMO of 2$^{2+}$ obtained by the present calculation has bonding nature (Fig. S6, ESI†). Inspection of the shape of the HOMO suggests that it is constructed via bonding interaction between 1P superatomic orbitals of Au$_{13}$ moieties. Based on Scheme 1b, the HOMO of 2$^{2+}$ corresponds now to a 2σ state. Meanwhile, both the HOMO−1 and HOMO−2 correspond to 1π$^*$ states; and the HOMO−3 refers to a 2σ$^*$ state (Fig. S6, ESI†). Therefore, the ordering of the energetic
states of HOMO and HOMO−3 has been interchanged. We consider this as a ligand effect: the energetically closely spaced orbitals, which are of superatomi 1P character, are sensitive to the influence of localized p-orbital states of individual sulfur atoms at the cluster waistline, and this lowers the energy of the 2σ* state.

Fig. 5b shows the calculated optical absorption spectra of 2+ and 3+. The calculated spectrum of 2+ reproduces well characteristic features of the experimental spectra (Fig. 3a). The spectrum of 3+ appears to be similar to that of 2+. Especially, the characteristic peak at ~1.7 eV for 2+ is still present for 3+ (odd number of electrons, with spin-polarization), which is inconsistent with the experimental observation (Fig. 5b). This contradiction suggests that oxidized form 3+ is not stable in solution and is transformed into another structure or structures.

The electrooxidation sample of 2+ was examined by TEM. In the TEM images (Fig. S8, ESI†), only Au clusters smaller than 2 nm were observed although the sample contained unoxidized 2+. This observation and the absence of a surface plasmon resonance band in the oxidized sample (Fig. 4b) suggest that aggregation of 2+ is not induced upon oxidation. The oxidation product obtained after bulk electrolysis of 2+ was further examined using XAFS. Fig. 6 shows the Au L3-edge extended X-ray absorption fine structure (EXAFS) oscillations and FT-EXAFS spectra of 2+ and the oxidation product. The results of the EXAFS analysis are summarized in Table 1. From these data, it is evident that the coordination numbers of the Au–Au and Au–ligand bonds did not change appreciably upon electrooxidation.

The experimental and theoretical results reported above suggest that Au259+ with the vertex-sharing biicosahedral motif undergoes irreversible structural change upon oxidation. It is reported that phosphine-protected Au clusters such as [Au(18)(PPh3)18Cl2]+ are electrochemically unstable,38 whereas thiolate-protected Au clusters such as [Au25(SR)18]− are electrochemically stable.38,39 Thus, difference in the electrochemical instability between Au239+ and Au259+ superatomic molecules may be associated with that in the protecting ligands. The Au239+ core is protected by three −SR–Au–SR– and six −SR–(Au–SR)2– oligomers, whereas the Au259+ core is protected by five RS, ten PR3 and two halides. One possible pathway is the isomerization of the Au25 core induced by the release of the phosphine ligand upon electrooxidation. Such electrochemically irreversible structural isomerization has been observed in [Au6(Ph2P(CH2)3PPh2)4]9+ (n = 2 and 4).40

**Conclusions**

The structural changes of Au118(SC2H4Ph)24 and [Au25(PPh3)10−(SC2H4Ph)3Cl]2+ upon electrooxidation were studied by spectro-electrochemical and XAFS measurements and DFT calculations. The face-sharing Au239+ bicosahedron protected by Au–SR oligomers retains the structure upon oxidation, indicating that oxidation-induced geometric relaxation is negligibly small in
contrast to the corresponding molecule F$_2$. In contrast, the vertex-sharing Au$_{13}$-$\text{by}$ bicosahedron protected by thiolates, phosphines and halides underwent irreversible structural change. This electrochemical instability is ascribed to the bonding scheme between two Au$_{13}$ units and/or the bonding nature of the protecting ligands.
