Statistical physics provides the concepts and methods to explain the phase behavior of interacting many-body systems. Investigations of Lee-Yang zeros—complex singularities of the free energy in systems of finite size—have led to a unified understanding of equilibrium phase transitions. The ideas of Lee and Yang, however, are not restricted to equilibrium phenomena. Recently, Lee-Yang zeros have been used to characterize nonequilibrium processes such as dynamical phase transitions in quantum systems after a quench or dynamic order-disorder transitions in glasses. Here, we experimentally realize a scheme for determining Lee-Yang zeros in such nonequilibrium settings. We extract the dynamical Lee-Yang zeros of a stochastic process involving Andreev tunneling between a normal-state island and two superconducting leads from measurements of the dynamical activity along a trajectory. From the short-time behavior of the Lee-Yang zeros, we predict the large-deviation statistics of the activity which is typically difficult to measure. Our method paves the way for further experiments on the statistical mechanics of many-body systems out of equilibrium.

Introduction.—Phase transitions are ubiquitous physical phenomena involving abrupt changes of a macroscopic system in response to small variations of an external control parameter [1,2]. A gas, for example, condenses into a liquid when cooled below a certain temperature and its density suddenly increases, Fig. 1(a). The phase transition is accompanied by large fluctuations of thermodynamic observables and an anomalous behavior of the free energy [3]. Early on, Lee and Yang realized that these exceptional features can be understood from the complex values of the control parameter for which the partition function of a finite-sized system vanishes [4,5]. In the thermodynamic limit, the complex zeros approach the real value of the control parameter for which a phase transition occurs, Fig. 1(b). Equilibrium Lee-Yang zeros are not only an important theoretical concept [6,7]. They can also be detected as demonstrated in a recent experiment on the two-dimensional Ising model [8,9].

The ideas of Lee and Yang have led to a unified understanding of a broad variety of equilibrium phenomena ranging from percolation [10,11] and complex networks [12,13] to protein folding [14,15] and Bose-Einstein condensation [16,17]. Moreover, it has been recognized that Lee-Yang zeros are not restricted to equilibrium phase transitions. They can also characterize nonequilibrium processes such as dynamical phase transitions occurring in quantum systems after a quench [18–20] or dynamic order-disorder transitions expected in glasses [21–24]. The partition function is then replaced by a nonequilibrium counterpart [25,26] and the phase transition may be driven by fields that bias the expectation.
dynamical trajectories [21–24], Fig. 1(c). In general, it can be hard to relate these fields to experimentally controllable parameters. Recently, however, it has been suggested that such phase transitions may be analyzed and detected within the framework of Lee-Yang zeros [27,28], Fig. 1(d).

In this Letter we experimentally determine the dynamical Lee-Yang zeros of a stochastic process in which individual Andreev events are detected and counted in real time [29]. The charge detection method that we use is by now well established and it allows for highly accurate statistical measurements [30–32]. In each Andreev event, a Cooper pair from a superconductor is transformed into two electrons in a normal-state metal or vice versa. The experimental setup consists of a metallic island coupled to superconducting leads via insulating tunnel barriers, Fig. 2(a). The experiment generates a large ensemble of dynamical trajectories that can be analyzed with the tools of statistical mechanics. Each trajectory is characterized by its dynamical activity [33], i.e., the total number of Andreev events that have occurred, Fig. 2(b). The system switches randomly between two distinct dynamical phases, an active phase with many Andreev events (transitions between the two excited states) and an inactive phase with no events (the ground state). We extract the dynamical Lee-Yang zeros from the fluctuations of the activity, Fig. 2(c). Importantly, from the motion of the dynamical Lee-Yang zeros at short times, we are able to infer their positions in the long-time limit. As we shall see, the Lee-Yang zeros converge to points that are slightly off from their positions in the long-time limit. As we shall see, the Lee-Yang zeros can predict the large-deviation statistics of the activity, which is otherwise difficult to measure. Our method can be applied to any experimental setup, where discrete events can be counted and a dynamical partition sum exists [30–32].

Statistical physics of trajectories.—Statistical mechanics describes the equilibrium state of a macroscopic system as an ensemble of microstates realized with a certain probability [1,2]. Likewise, the evolution of a stochastic process can be considered as an ensemble of trajectories characterized by the dynamical partition sum [22,33–37]

\[ Z(s, t) = \sum_K P(K, t) e^{-iK}. \]

Here, \( P(K, t) \) is the probability of realizing a trajectory of length \( t \) with \( K \) random events. The intensive field \( s \) couples to the extensive observable \( K \), similarly to how the magnetic field and the total magnetization are conjugate variables in equilibrium statistical mechanics. The corresponding dynamical free energy is defined as [33]

\[ \mathcal{F}(s, t) = \ln Z(s, t). \]

For long observation times, the average number of events \( \langle K \rangle \) becomes macroscopically large, and a system may exhibit a transition between different phases at a critical biasing field for which the dynamical free energy \( \mathcal{F}_s(t) \) becomes nonanalytic. Experimentally, however, it is not clear how to tune the biasing field and the measurements presented here are all carried out at \( s = 0 \). Still, it is possible to infer the position of the Lee-Yang zeros from the fluctuations of the activity.

To this end, we consider the cumulants of the activity

\[ \langle K^n \rangle(t) = (-1)^n \partial^n_s \mathcal{F}(s, t)|_{s=0}. \]

(3)

given by the derivatives of the dynamical free energy at \( s = 0 \). In addition, we factorize the dynamical partition sum in terms of its Lee-Yang zeros \( s_j(t) \) as [38]

\[ Z(s, t) = e^{nc(t)} \prod_j [s_j(t) - s]/s_j(t). \]

(4)

Here, the function \( c(t) \) depends only on the observation time \( t \) and the dynamical Lee-Yang zeros come in complex conjugate pairs since \( [Z(s, t)]^* = Z(s^*, t) \). For \( n > 1 \), the cumulants can now be written as [27,39–41]

\[ \langle K^n \rangle(t) = (-1)^{(n-1)} \sum_j \frac{(n-1)!}{s_j^n(t)}. \]

(5)

This relation expresses the measurable cumulants in terms of the dynamical Lee-Yang zeros. The high-order cumulants are governed by the pair of Lee-Yang zeros \( s_0(t) \) and
FIG. 3. Determination of dynamical Lee-Yang zeros. (a) The leading pair of dynamical Lee-Yang zeros (blue) in the complex plane of the biasing field $s$. The Lee-Yang zeros are extracted from the cumulants of the activity in Fig. 2(c) for $t = 1, \ldots, 35$ ms. The extracted Lee-Yang zeros are unchanged if the cumulant order is increased, ensuring us that subleading zeros can safely be neglected. At longer times, subleading zeros start to interfere and the extraction method is no longer accurate. The Lee-Yang zeros converge towards the points $s_1^c$ and $s_2^c$ indicated in red. (b) The convergence points are obtained by linearly extrapolating the dependence of the real part and the imaginary part on the inverse observation time for $t = 10 - 35$ ms [27]. By taking the inverse time to zero, we find the convergence points $s_1^c = -0.23 \pm 0.15i$ shown with red in both panels.

$s_n^0(t)$ closest to $s = 0$, since this pair dominates the sum for large $n \gg 1$, such that

$$\langle K^n \rangle(t) = (-1)^{n-1}(n-1)! \frac{2 \cos |n \arg \{s_0(t)\}|}{|s_0(t)|^n}. \quad (6)$$

From this relation, it follows that the Lee-Yang zeros can be obtained from the expression [27]

$$\begin{bmatrix} -2\text{Re}[s_0] \\ |s_0|^2 \end{bmatrix} = \begin{bmatrix} 1 - \frac{\kappa_n^+}{n} \\ 1 - \frac{\kappa_n^-}{n+1} \end{bmatrix}^{-1} \begin{bmatrix} (n-1)\kappa_n^+ \\ nk_{n+1} \end{bmatrix} \quad (7)$$

involving the ratios $\kappa_n^\pm(t) = \langle K^{n+\pm1} \rangle(t)/\langle K^n \rangle(t)$ of four successive cumulants. The method is essentially independent of the system under consideration and it can be applied to a variety of equilibrium and nonequilibrium situations. For example, by measuring the cumulants of the magnetization in a spin lattice, one may extract the leading pair of Lee-Yang zeros in the complex plane of the magnetic field.

**Determination of dynamical Lee-Yang zeros.**—Our experimental setup is shown schematically in Fig. 2(a). In the ground state, the normal-state island is occupied by 0 (excess) electrons. The tunneling of a single electron between the island and the leads can bring the island to one of its excited states with ±1 electron. The excited states are energetically degenerate and transitions between them may occur through an Andreev event in which two electrons on the island are transformed into a Cooper pair in one of the leads or vice versa. The charge state of the island is detected using a nearby single-electron transistor whose conductance depends on the number of electrons on the island. By monitoring the current in the single-electron transistor in real-time, we may thus count the individual Andreev events, Fig. 2(b). The probability distribution $P(K, t)$ for the number of Andreev events $K$ was measured as a function of the observation time $t$ in Ref. [29]. The corresponding high-order cumulants $\langle K^n \rangle(t)$ of order $n = 4, 5, 6, 7$ are shown in Fig. 2(c). From these four cumulants, we can extract the leading pair of dynamical Lee-Yang zeros using Eq. (7).

Figure 3(a) shows the motion of the leading pair of dynamical Lee-Yang zeros in the complex plane of the biasing field $s$. The dynamical Lee-Yang zeros initially move fast, but eventually slow down as they approach the points marked with red. To pinpoint the exact convergence points, we analyze in Fig. 3(b) the real part and the imaginary part of the dynamical Lee-Yang zeros as functions of the inverse observation time. After an initial transient, where the Lee-Yang zeros are still far from the convergence points and not yet well separated, both the real part and the imaginary part become linearly dependent on the inverse observation time. The convergence points indicated with red circles in Fig. 3. The convergence points are slightly off the real axis. The small imaginary part translates to a smeared transition as we discuss below.

**Large-deviation statistics.**—The extracted convergence points have important implications for the large-deviation statistics of the dynamical activity. To see this, we consider a generic model of a system with two distinct dynamical phases as described by the matrix equation
\[ \frac{d}{dt} \rho(s, t) = \mathcal{W}(s) \rho(s, t), \]  
\[ \mathcal{W}(s) = \begin{bmatrix} \mathcal{H}_1(s) - \Gamma_1 & \Gamma_2 \\ \Gamma_1 & \mathcal{H}_2(s) - \Gamma_2 \end{bmatrix}. \]

Here, the vector \( \rho(s, t) = [p_1(s, t), p_2(s, t)]^T \) contains the probabilities of being in either of the two phases for \( s = 0 \), where Eq. (8) reduces to a standard master equation. The fluctuations in each phase are described by the generators \( \mathcal{H}_{1,2}(s) \) and switching between them occurs with the rates \( \Gamma_{1,2} \). This description is valid for systems with a clear separation of time scales [44-46]. Specifically, the inverse of the rate matrix occurs for trivial reasons, such as when a symmetry splits the large number of degrees of freedom. (In finite systems, it can occur for trivial reasons, such as when a symmetry splits the large number of degrees of freedom. (In finite systems, it can occur for trivial reasons, such as when a symmetry splits the large number of degrees of freedom.) When the convergence points approach the origin, the ellipse reduces to the straight line \( \phi(J) = -s_R^2|J - J_1| \) with \( J_1 = J_1 \) for \( s_R < 0 \) and \( J_1 = J_2 \) for \( s_R > 0 \). If one could tune the field \( s \) across \( s_R^c \), there would be an abrupt change in the average activity from \( J_1 \) to \( J_2 \), corresponding to a first-order phase transition. Such a singularity typically only occurs in systems with a large number of degrees of freedom. (In finite systems, it can occur for trivial reasons, such as when a symmetry splits the dynamics into disconnected ergodic components, see, however, Ref. [48].) When the convergence points \( s_c \) and \( s^c_R \) remain complex, the ellipse has a finite width as in Fig. 4. In this case, there is a crossover at \( s_R^c \) corresponding to a smeared first-order transition. By decreasing the switching rates, the transition points would move closer to the origin and a sharp transition would emerge.

**Conclusions.**—We have realized a scheme for determining the leading Lee-Yang zeros in experiment and thereby bridged a gap between theoretical concepts in statistical physics and measurements of fluctuations in many-body systems. Our method can be applied to a large range of systems with a clear separation of time scales [44-46]. Specifically, the inverse of the rate matrix occurs for trivial reasons, such as when a symmetry splits the large number of degrees of freedom. (In finite systems, it can occur for trivial reasons, such as when a symmetry splits the large number of degrees of freedom.) When the convergence points approach the origin, the ellipse reduces to the straight line \( \phi(J) = -s_R^2|J - J_1| \) with \( J_1 = J_1 \) for \( s_R < 0 \) and \( J_1 = J_2 \) for \( s_R > 0 \). If one could tune the field \( s \) across \( s_R^c \), there would be an abrupt change in the average activity from \( J_1 \) to \( J_2 \), corresponding to a first-order phase transition. Such a singularity typically only occurs in systems with a large number of degrees of freedom. (In finite systems, it can occur for trivial reasons, such as when a symmetry splits the dynamics into disconnected ergodic components, see, however, Ref. [48].) When the convergence points \( s_c \) and \( s^c_R \) remain complex, the ellipse has a finite width as in Fig. 4. In this case, there is a crossover at \( s_R^c \) corresponding to a smeared first-order transition. By decreasing the switching rates, the transition points would move closer to the origin and a sharp transition would emerge.
equilibrium and nonequilibrium settings, including dynamical phase transitions in quantum systems after a quench or dynamic order-disorder transitions in glasses. As such, our work facilitates several intriguing opportunities for further experiments on the statistical mechanics of many-body systems.
