We demonstrate nonadiabatic charge pumping utilizing a sequence of coherent oscillations between a superconducting island and two reservoirs. The pumping rate for each elementary cycle is limited by the coupling between the island and the reservoirs given by the Josephson energy. Our experimental and theoretical studies show that relaxation can be employed to reset the pump in order to avoid accumulation of errors due to nonideal control pulses. Thus our results demonstrate the effects of nonadiabatic quantum pumping and dissipation.

Introduction. The possibility to measure and control the charge states of small islands with single-electron precision has given rise to the development of several practical devices in the recent decades. For example, pumps and turnstiles have been introduced that aim to transfer an integer number of electrons per cycle in metallic, semiconducting, and hybrid devices. Some of these systems hold great potential to be used as a standard of metrology, they are unique in the sense that their operation is typically dominated by coherent quantum effects. The quantum behavior is manifested, for example, in the fundamental relation between the accumulated Berry phase and quantum behavior is manifested, for example, in the fundamental relation between the accumulated Berry phase and quantum behavior is manifested, for example, in the fundamental relation between the accumulated Berry phase and the adiabatically transferred charge. We find that by initializing the system after each pumping cycle, the accumulation of errors can be avoided leading to a greatly improved pumping efficiency.

Theoretical model. The measured devices are based on a Cooper pair transistor that, in addition to the dc gate, has also a pulse gate as shown in Fig. 1. The superconducting island of the transistor (red bar) is separated on one side by a single junction with Josephson energy $E_J$ and on the other side by a superconducting quantum interference device (SQUID). The SQUID works effectively as a single junction with a flux-controllable Josephson energy $E_{12}$, which allows us to tune $E_{12}$ by an external magnetic field $B$. The left lead of the transistor is grounded and the right lead is biased by a voltage $V_b$ (see Fig. 1). A similar device but with symmetric bias of the leads is analyzed in Ref. 30. We present the Hamiltonian of our system in the form

$$
\hat{H} = 4E_C (\hat{n} - n_g)^2 - 2eV_b \hat{n} + \sum_{k,m} \left( \frac{E_{12}}{2} |k + 1,m\rangle \langle k,m| + E_{12} \frac{1}{2} |k + 1,m\rangle \langle k,m + 1| + c.c. \right),
$$

where the charging energy of the island $E_C$ is given by the capacitance $C_1$ of lead 1 (grounded), $C_2$ of lead 2 (biased), the gate capacitances $C_g$ and $C_p$, and the self-capacitance of the island $C_0$ as $E_C = \epsilon^2 / 2 (C_1 + C_2 + C_g + C_p + C_0)$. The number operators of the excess Cooper pairs on the island $\hat{n} = \sum_{k,m} k |k,m\rangle \langle k,m|$ and on lead 2 $\hat{n} = \sum_{k,m} m |k,m\rangle \langle k,m|$ are expressed with the charge basis $|k,m\rangle$ of the number of Cooper pairs on the island ($k$), and on lead 2 ($m$). The induced gate charge in units of $e$ is given by $n_g = (V_b C_g + V_b C_p + V_b C_2) / 2e$. The first term in the sum of the Hamiltonian (1) represents the Josephson coupling of the island to lead 1 and the second is coupling between the island and lead 2.

Pumping cycle. The nonadiabatic pumping cycle can be realized with the composite pulse shown in Fig. 1(b) and referred to as the base sequence. Figure 1(c) describes how
Cooper pairs are transferred to and from the island during the cycle: First, the electrostatic potential of the island is brought to a point \( n \approx 0 \) (I), which is far away from charge degeneracy. The potential is shifted to \( n \approx 1 \) (II) by coherent tunneling of a Cooper pair through the second junction. During the second part of the pulse, we nonadiabatically shift the gate charge to \( n_g = 1/2 \) (III), where the effective Hamiltonian is 
\[ E_{12}(1, -1)(0, -1) + |0, 1, -1)\) in order to induce coherent oscillations through the first junction. Finally, after the interval \( \tau = \pi \hbar / E_{12} \), the charge state \( |1, -1) \) is transferred into \( |0, -1) \) (IV). Thus the charge-transfer process induced in the whole cycle is \( |0, 0) \rightarrow |1, -1) \rightarrow |0, -1) \). Repeating the manipulation sequence one can obtain states \( |0, m) \) with any \( m \). Hence ideally one obtains an average dc current of 
\[ I_p = \frac{-e I_d}{\pi \hbar} \]. To pump forward, i.e., along the bias voltage, we can reverse the order of the pulse height changes \( V_{p1} \) and \( V_{p2} \), which results in transferring a Cooper pair from lead 1 to lead 2. In our experiments, gating errors prevent us from making many repetitions, and the average pumped current is determined by the waiting time in between the pulse sequences as discussed in the following.

**Experimental methods.** The device is fabricated by two-angle evaporation of Al with a thickness of 10 nm for the island [red (dark gray) patterns in Fig. 1] and 40 nm for the leads [yellow (light gray) patterns in Fig. 1] on an oxidized silicon substrate using a standard trilayer resist structure. The pattern is defined by electron-beam lithography in the top polymethylmetacrylate resist and then transferred into a Ge layer by reactive ion etching. The lead and gate electrodes are connected via filtered twisted-pair dc lines to room-temperature electronics for biasing and current amplification. The pulse gate is connected to the unterminated central line of the prefabricated gold-patterned on-chip coplanar waveguides. The waveguide is ribbon bonded to a coaxial line attenuated by 20 dB at 4 K. Composite pulses are generated by superimposing two channels of a picosecond pulse pattern generator with a rise time of about 20 ps measured at room temperature. The sample is mounted in vacuum in a dilution refrigerator with a base temperature of about 30 mK. We extracted the following parameter values for the sample studied in this work: \( E_C = 139 \mu \text{eV}, C_g = 3.3 \text{ aF}, \) and \( E_{11} = E_{12} = 26 \mu \text{eV} \).

**Results.** The current through the device without applying the pumping sequence is shown in Fig. 2(a) as a function of the bias voltage \( V_b \) and the dc gate-induced charge \( \Delta Q_{g}/2e = V_g C_g/2e \) controlled by \( V_g \). Around \( V_b = 0 \), a 2-ns-oscillatory supercurrent is visible, confirming that our device is not poisoned by quasiparticles. At higher bias voltages Cooper pair tunneling resonances become energetically allowed, accounting for some of the other features in Fig. 2(a). In particular, the V-shaped regions around the charge degeneracy points originate from resonant tunneling of one Cooper pair on or off the island. The strong 1-ns-oscillatory features at \( eV_b = 2E_C \) occur at the crossing of two such Cooper pair tunneling resonances[31,32].

For Cooper pair pumping, we utilize the two-level base sequence discussed above and shown in Fig. 1(b), but in each cycle we apply \( n \) subsequent base sequences followed by a waiting period with length \( T_r \) at voltage \( V_g = V_{gA} \) to allow the system to relax back to the ground state. The current through the device with the pumping cycle applied is shown in Fig. 2(b) as a function of the bias voltage and the dc gate-induced charge \( \Delta Q_{g}/2e \) for \( n = 1, T_r = 8 \) ns, and the pulse duration \( \tau = 100 \) ps. The pulse levels at the pulse generator are \( V_{p1} = 0.8 \) V and \( V_{p2} = 2 \) V. The corresponding dimensionless gate induced charges defined according to 
\[ n_{p1} = V_{p1} C_p/2e \] (\( i = 1,2 \)) are \( n_{p1} = 0.11 \) and \( n_{p2} = 0.28 \).

In addition to the Cooper pair tunneling resonance current \( \Delta Q_{o}/2e = 0.5 \) observed also without pulses, a positive current peak \( (\Delta Q_{o}/2e = 0.13 \) and additional smaller peaks) and a negative current peak \( (\Delta Q_{o}/2e \approx 0.3) \) are observed. For better visibility, a cut along the \( \Delta Q_{o}/2e \) axis for \( eV_b/E_C = \).
level peak to a process in which an excess Cooper pair tunnels on a time scale of hundreds of picoseconds. Here, we employed pumping. The coherent oscillations have a period of 160 ps and decay on the time scale of hundreds of picoseconds. We find that the positive current peak should appear during the waiting period as shown in Fig. 1(d). According to this calibration, the expected position of the positive current peak can be calculated as shown by the slanted dashed line in Fig. 2(b). The good agreement with the experimental data corroborates our interpretation of the transport process giving rise to this peak.

Since the pumping cycle introduced in Figs. 1(b) and 1(c) produces a negative current, we attribute the negative current peak in Fig. 2(b) to pumping. This claim is supported by the fact that pumping is effective only when the pulse amplitude $V_{p2} - V_{p1}$ corresponds to the difference in the potentials between the leads given by $\mu_1 - \mu_2 = 2eV_b$. For $(V_{p2} - V_{p1}) = 1.2 \text{ V}$, pumping is therefore expected to be effective at a bias voltage $eV_b / EC = (n_{p2} - n_{p1}) = 0.66$ in good agreement with the data in Fig. 2(b), where the positive current peak is visible for all bias voltages but the negative current peak is peaked near $eV_b / 8 EC = 0.66$. In addition, the position $\Delta Q_0/2e$ of the pumping peak should be at $\Delta Q_0/2e = 1/2 - n_{p1} - eV_b/8 EC = 0.31$ close to $\Delta Q_0/2e = 0.32$ as observed in the experiment giving further support to our assignment of the negative current peak to pumping. We have repeated the measurements shown in Fig. 2(b) for pulse amplitudes ranging from $V_{p2} - V_{p1} = 0.5 \text{ V}$ to $2 \text{ V}$ giving similar results consistent with the interpretation described above (data not shown).

To demonstrate that the Cooper pair pumping is coherent, we measured the pumped current as a function of the pulse length $\tau$ as shown in Fig. 2(d). The bias voltage is set to $eV_b / EC = 0.46$ and the corresponding pulse amplitudes are set to $V_{p1} = 0.75 \text{ V}$ and $V_{p2} = 1.5 \text{ V}$. We obtain a negative current with the base sequence shown in Fig. 1 and a positive current with a similar sequence but with the order of the pulse levels $V_{p1}$ and $V_{p2}$ reversed [insets in Fig. 2(d)]. In both cases, oscillations of the current as a function of the pulse length $\tau$ are observed as expected for the Hamiltonian (1). The oscillations have a period of 160 ps and decay on the time scale of hundreds of picoseconds, faster than previously observed in charge qubits. We attribute the fact that the maximum amplitude of the pumped current is observed at $\tau = 100 \text{ ps} > h/E_j$ to the finite rise time of the pulses leading to a smaller effective amplitude of short pulses. The decay is potentially dominated by background charge fluctuations which change the resonance condition for the leads, and hence imply rather fast dephasing of the Cooper pair oscillations through the junctions, as supported by our numerical simulation of the driven quantum evolution [black line in Fig. 2(d)]. The simulations are carried out by solving the temporal evolution of the system density matrix from the Hamiltonian (1). The evolution is assumed unitary during the base cycles and relaxation is introduced during the waiting period. The resulting density matrices are
averaged over a number of background charge states to obtain the final pumped charge. The temporal shapes of the voltage pulses are taken from the measured shapes at room temperature and filtered numerically according to the specifications of the coaxial cables employed in the experiments.

For a Cooper pair pumping sequence, composed of \( n \) base sequences, the maximal expected current is given by \( I_{\text{max}} = 2en/T_r \), since \( \tau \ll T_r \). Thus we characterize the pumping efficiency by \( \eta = I/I_{\text{max}} \), where \( I \) is the actual pumped current. In Fig. 3(a), the efficiency for forward and backward pumping with \( n = 1 \) is shown as a function of \( T_r \). The efficiency for both directions of pumping approaches exponentially the maximal efficiency \( \eta_{\text{max}} \) with increasing \( T_r \). This dependence can be phenomenologically described by \( \eta(T_r) = \eta_{\text{max}}(1-e^{-T_r/T}) \), where \( T \approx 10 \text{ ns} \) is a characteristic time constant which is of the order of the energy relaxation time found in previous experiments for charge qubits. The maximum efficiencies are \( \eta_{\text{max}} = 0.8 \) and \( \eta_{\text{max}} = 0.6 \) for forward and backward pumping, respectively. Due to the accumulation of pumping errors, this efficiency decreases for larger \( n \) of base sequences in a cycle as shown in the inset of Fig. 3 up to \( n = 4 \) for backward pumping. The maximum efficiency \( \eta_{\text{max}} \) is observed to be proportional to \( \eta_0^n \), where \( \eta_0 = 0.74 \) is the efficiency per pulse. We attribute this nonideal efficiency to the finite bandwidth of the control pulses limited by the cryogenic transmission line and dephasing due to background charge fluctuations as supported by our numerical calculations.

The different efficiencies for forward and backward pumping in Fig. 3 can be attributed to the finite rise time of the pump pulses. In the case of backward pumping, during the first part of the pulse sequence, the energy level of the island is swept through the degeneracy point [Fig. 1(c), I-II] resulting in a possible tunneling process of a Cooper pair from the first lead to the island. Since this process transfers Cooper pairs in the direction of the applied bias voltage, the effective current for the backward pumping is decreased.

Conclusions. We have introduced a device for nonadiabatic Cooper pair pumping and demonstrated its working principles both theoretically and experimentally. Due to accumulation of pumping errors, the average pumped current was found to be determined by the internal relaxation rate of the device rather than the Josephson energy. Although more sophisticated, error correcting, pumping sequences may improve the operation, it remains to be shown whether nonadiabatic operation provides advantage over adiabatic Cooper pair pumping. In the future, it would be interesting to study the possible relation between the geometric phases and the nonadiabatically or non-cyclically pumped charge as has been already demonstrated in the adiabatic case.
