**ABSTRACT**

The sustainable synthesis of polymers is a field with growing interest due to the need of modern society to preserve the environment whilst making used products and food sustainable for the future generations. In this work we investigate the possibility of synthesizing aliphatic polyesters derived from various dicarboxylic acid diesters and diols in a solvent-free reaction system. *Candida antarctica* lipase B was selected as biocatalyst and its selectivity towards the carbon and ester chain length were elucidated. The selected enzyme was able to synthesize various polyesters combining C\textsubscript{4}C\textsubscript{10} diesters and C\textsubscript{4}C\textsubscript{8} diols. All combinations led to monomer conversions above 90% in 24 h with the best number average molecular weights (M\textsubscript{n}) being obtained through the combination of dimethyl adipate and 1,8-octanediol leading to a M\textsubscript{n} of 7141 Da. Differential scanning calorimetry analysis shows a clear trend with an increase in melting temperature of the polymers that correlates with both the increase of the M\textsubscript{n} or of the polymer’s constitutional repeat unit carbon chain length. Thermogravimetric analysis and rheology measurements performed on selected samples also confirm the trend showing a variation of the polymer’s degradation temperatures and viscosity profiles.

1. Introduction

The application of biocatalysts in organic synthesis offers several advantages compared with traditional chemo-catalysts such as milder reaction conditions with regards to temperature (usually T < 100 °C), pressure and pH (normally 3–8). Such conditions often lead to remarkable energy efficiency, high enantio-, regio- and chemo-selectivities as well as controlled stereochemistry. These features allow the development of new functional compounds for pharmaceuticals, agrochemicals and polymers using nontoxic natural catalysts with a significant “green” appeal having commercial benefits and satisfying ecological requirements [1].

Despite studies focused on the use of glycosidases for the synthesis of natural and unnatural polysaccharides [2], as well as oxidoreductases for the polymerisation of phenol derivatives [3] and vinyl monomers [1] (mainly using laccases and peroxidases), the most investigated area of enzymatic synthesis is the production of polyesters via both polycondensation (transesterification) and ring opening polymerisations (ROPs) [4,5]. These areas have predominantly emerged thanks to the discovery and commercial availability of *Candida antarctica* lipase B (CaLB). Over recent years the extraordinary properties of this enzyme were brought to light from several research teams in the kinetic resolution of organofluorine rac-alcohols [6], the synthesis of glucoside esters [7] and the enantioselective synthesis of a β-amino acid ester via a solvent-free chemo-enzymatic reaction among others [8].

Further to this, CaLB has been shown to be an active catalyst for the synthesis of a wide range of aliphatic [9], aliphatic functional [10,11] (e.g. polymers containing lateral functionalities such as vinyl and hydroxy groups) and aliphatic-aromatic polyesters [12,13] and polyamides [14]. In recent years these polyesters and polyamides have been derived preferentially from renewable monomers such as 2,5-furandicarboxylic, adipic and succinic acids and 1,4-butanediol among others [5].

Despite several other enzymes belonging to the hydrolyses family, namely cutinases from *Humicola insolens* [15], *Fusarium solani pisi* [16] and *Thermobifida cellulosilytica* [17], being reported to be active for the synthesis of various polyesters and polyamides in their lyophilized and immobilized forms (ranging from cross-linked enzyme aggregates to...
covalent binding [18,19]), the choice of the chemist is still often the readily available CaLB adsorbed on a methacrylic resin known under the tradename of Novozym® 435. This biocatalyst has been shown to be active and stable in several different conditions ranging from water-based to anhydrous organic media and up to temperatures of ∼100 °C.

Among the many synthesis studies both on polycondensation and ROPs that were performed over the years using this enzyme, we found there is a lack of comparative studies on the range of monomers shown in Scheme 1 (most of which bio-based) [20] for the synthesis of aliphatic polyesters.

Despite the many studies on the topic, there remains an absence of any detailed systematic study into the implications of changing the diester and/or diol whilst applying identical methodologies for the polymerisation. In the present study we investigated the CaLB-catalyzed polycondensation of various methyl-, ethyl- and butyl-dicarboxylic acid esters with various linear diols having a carbon chain length of 4, 6 or 8, shedding light on how reactive different size diesters are when employing enzymatic catalysis in a solvent-free reaction system (Scheme 2). These results will/have help(ed) us to understand the strengths and weaknesses of using this, until now, sporadically investigated enzyme for polyester synthesis.

**Scheme 1.** Dicarboxylic acid diesters (top) and linear diols (bottom) used in this study for the enzymatic synthesis of aliphatic polyesters in solvent-free systems using Candida antarctica lipase B as biocatalyst.

**Scheme 2.** The three parameters that were investigated in the present study, namely (1) ester carbon chain length; (2) diester carbon chain length and (3) diol carbon chain length.
2. Materials and methods

2.1. Chemicals and enzymes

1,4-butanediol (BDO) was purchased from Alfa Aesar. Dimethyl adipate (DMA) and 1,8-octanediol (ODO) were purchased from Acros Organics. Dimethyl succinate (DMS) was purchased from Fluka. All other chemicals and solvents were purchased from Sigma-Aldrich and used as received if not otherwise specified. Candida antarctica lipase B (CaLB) immobilized onto methacryl. res was purchased from Sigma-Aldrich (product code L4777) (N435). The enzyme was dried under vacuum for 96 h at 25 °C and stored in a desiccator prior to use.

2.2. Enzymatic polycondensation of aliphatic polyesters

0.006 mol of dicarboxylic acid ester (A) and 0.006 mol of linear diol (B) (diester:dial ratio = 1.0:1.0) were accurately weighted in a 25 mL round bottom flask. The mixture was then stirred at 85 °C until a homogeneous melt was obtained. 10% w w⁻¹ (calculated on the total amount of the monomers) of N435 was then added and the reaction was run for 6 h at 1 Atm. A vacuum of 20 mbar was subsequently applied for an additional 18 h maintaining the reaction temperature at 85 °C (total reaction time: 24 h). The reaction product was recovered by adding THF (or DCM in the case of the 24 h succinate-BDO polymers) in order to dissolve the solid reaction products. The biocatalyst was then removed via a filtration step and the solvent evaporated under vacuum. The polymers were then characterised without additional purification steps.

2.3. Nuclear magnetic resonance (NMR) spectroscopy

¹H NMR analyses were performed on a JEOL JNM-ECS400A spectrometer at a frequency of 400 MHz. CDCl₃ was used as NMR solvent for all synthesized polymers.

2.4. Gel permeation chromatography (GPC)

GPC was carried out using a PSS SDV High set composed of 3 analytical columns (300 × 8 mm, particle diameter 5 µm) of 1000, 10⁵ and 10⁶ Å pore sizes, plus guard column (Polymer Standards Service GmbH, PSS) installed in a PSS SECurity SEC system. Elution was with THF at 1 mL min⁻¹ with a column temperature of 23 °C and detection by refractive index. 20 µL of a ~2 mg mL⁻¹ sample in THF, adding a drop of toluene as reference standard, was injected for each measurement and eluted for 50 min. Calibration was carried out in the molecular weight range 370–2,520,000 Da using the ReadyCal polystyrene standards supplied by Sigma Aldrich and referenced to the toluene peak.

2.5. Differential Scanning Calorimetry (DSC)

Traditional DSC analyses were performed on a TA Instruments Q2000 under nitrogen atmosphere. The heating rate used was 5 °C min⁻¹ over a T range of −60 to 200 °C. Cooling rate was set at 5 °C min⁻¹ over the same T range. Sample mass was of 5–10 mg for all measured samples. The polymer’s melting ranges were calculated from the second heating scan using the value at peak maximum option.

2.6. Thermogravimetric analysis (TGA)

TGA was performed on a PL Thermal Sciences STA 625 thermal analyzer. ~10 mg of sample was weighted in an aluminium pan. The sample was then placed into the furnace with a N₂ flow of 100 mL min⁻¹ and heated from 21 to 625 °C at a heating rate of 10 °C min⁻¹. From the TGA profiles the temperatures at 5% and 50% mass loss (TDS and TDS0) were subsequently determined.

2.7. Rheology measurements

Rheological rotational measurement under controlled shear rate were recorded using a Brookfield R/S-CPS + Rheometer fitted with a Peltier P-TS2 temperature controller and cone-plate geometry where the cone used had a 25 mm diameter, 2° angle and 0.045 mm gap height. The polymer samples were ground with a pestle and mortar prior to being loaded onto the pre-heated (80 °C) bottom plate. In all cases, a constant shear rate of 100 s⁻¹ was maintained throughout the experiments with each polymer melt being initially held at 80 °C (under shear) for 120 s before the temperature was decreased by 0.01 °C s⁻¹.

3. Results and discussion

The CaLB-catalysed polycondensation of methyl-, ethyl- and butylsuccinic (C₄), adipic (C₆) and sebacic (C₁₀) dicarboxylic acids esters with linear diols having a carbon chain length of 4, 6 or 8 atoms were investigated. In order to be environmentally friendly, all reactions were performed in bulk (i.e. solvent-less). All monomers were melted at 85 °C before adding the biocatalyst that allowed the initiation of the step-growth polycondensation. From the ¹H NMR spectra analysis it is possible to observe that for all reactions excellent monomer conversion values (> 90%) were obtained with the methyl and ethyl esters consistently giving slightly higher conversions than the equivalent butyl esters for all the dicarboxylic diesters investigated (Fig. 1).

The 2-step polycondensation protocol (1st-oligomerization and 2nd-chain elongation) reported in Scheme 3 was found suitable for all the reactions (see Table 1). The polycondensation reactions occur via transesterification of dicarboxylic acids diesters with aliphatic diols and follow a step-growth polymerisation mechanism (the same as some other similar synthetic polymers such as polyamides and polyurethanes). In fact with low DP (~5–10) the conversion is already >80–90% and further increase in DP (two fold) influences only minor the monomer conversion. This allows the initial oligomerisation of most of the monomers without loss of any of the starting compounds. After oligomerisation is achieved, vacuum is applied to effectively remove the alcohol by-product and enables the elongation of the polymeric chain length. The biocatalyst is indeed able to catalyse synthetic reactions starting from long polymeric chains as recently reported by Vastano et al. who coupled dimethyl itaconate and poly(ethylene glycol) to poly(hydroxyalkanoates) having Mn of 50188 Da and Mw of 117720 Da produced using an engineered strain of Escherichia Coli [21].

The number average molecular weight (Mₙ) (Fig. 2) and the weight average molecular weight (Mₙ) (see Fig. S2 in ESI) of the polymers were determined via GPC analysis. The Mₙ trend reported in Fig. 2 agreed well with the ¹H NMR spectroscopy monomer conversion analysis reported in Fig. 1. The methyl and ethyl diesters lead to the

Fig. 1. ¹H NMR analysis of the crude polycondensation products after CaLB-catalyzed polycondensation reactions after 24 h. Reactions without catalyst led to no detectable transesterification products. All reactions were performed in duplicates. Statistical analysis reporting the mean value ± standard deviation for all reactions can be found in ESI, Fig. S1 and the complete spectra assignment in Fig.S5.
The generally observed trend for the synthesised polymers based on HDO and ODO having higher molecular masses than the BDO equivalents (with the exception of the adipate-based polymers that showed similar molecular masses) reflects very well the data reported by Feder and Gross for the polycondensation of sebacic acid and various diols using N435 at 70 °C. In this previous work, a comparison between adipic and sebacic acid was made and fully agrees with our observation that the adpic acid diesters lead to higher molecular weight products than the sebacic diesters when methyl and ethyl esters were used while no significant differences were observed when butyl esters were used.

It was noticed that CaLB, when operating in a solventless reaction system, led to smaller differences between the different ester chains than when using cutinases and serin-hydrolase enzymes belonging to the same family. In fact, whereas CaLB leads to similar conversions with BDO, HDO and ODO, cutinases have a preferred substrate. Cutinase from Humicola insolens (70 °C, in bulk, diol diacid 1:1 mol/mol, 1% w/w of enzyme-to monomer, application of vacuum after 2 h) produces polymers with higher molecular weight when ODO is used as a diol while cutinase 1 from Thermobifida cellulosolvens (The_cut1) (70 °C, in bulk, diol diacid 1:1 mol/mol, 10% w/w of enzyme-to monomer, application of vacuum for 2 h) prefers BDO, leading to only short oligomers when HDO and ODO are used in combination with dimethyl adipate. For The_cut1, it was recently reported that the structure of the diol is relevant for the chain length, but the conversion is not much affected.

In order to be able to analyze the differences between all reactions, including the formation of aforementioned insoluble poly(butylene succinate), some selected reactions (reported in Table 1) were run for only 6 h at 85 °C and atmospheric pressure in order to stop the reaction after the initial oligomerisation phase.

From the collected data it is possible to see that the insolubility of poly(butylene succinate) in THF, even after stirring for several days, is not due to the high molecular weight of the polymers. It is well known that the dissolution of polymers depends not only on their physical properties, but also on their polarity, molecular weight, branching, crosslinking degree and crystallinity. In this particular instance, given the crystalline nature of all produced polymers it is probable that the insolubility of the succinate-based aliphatic oligoesters after 24 h reaction was indeed a result of high crystallinity rather than the oligomers as evidenced by the molecular masses data reported in Table 1 (and the DSC data reported later). The calculation of the DP of the reactions after 6 and 24 h fully confirms the trend previously reported.

**Electronic Supplementary Information (ESI) available:** Details of: 1H-NMR spectroscopy conversions (Fig. S1), Mₘ (Fig. S3) and Mₘ (Fig. S2 and S4) GPC data, DSC-determined polymer’s melting temperatures (Table S1) and TD5 and 50 (Table S2) are reported in ESI. All data gathered via funding from grants EP/L017393/1 and BB/N023595/1 is contained within the manuscript or the ESI. Supplementary data associated with this article can be found, in the online version, at https://doi.org/10.1016/j.eurpolymj.2018.07.009.

The synthesis of polymers having higher molecular weight relative to the butyl diesters. This effect of the size of the alkyl group of the diester (-methyl, -ethyl and -butyl) becomes less marked when increasing the relative boiling points of the alcohol by-products with methanol (BP = 64.7 °C) and ethanol (BP = 78.4 °C) being significantly less volatile than butanol (BP = 117.7 °C) and therefore easier to remove from the reaction system, especially when considering a reaction temperature of 85 °C was used. The polymers synthesized using the shortest dicarboxylic esters, dimethyl succinate (DMS), diethyl succinate (DES) and dibutyl succinate (DBS) together with 1,4-butandiol (BDO) were not soluble in the GPC mobile phase (THF) and therefore were not characterised using this technique.

via 1H NMR spectroscopy and GPC for all of the other reactions carried out (Table 1).

In addition to monomer conversion and molecular weight analysis, differential scanning calorimetry analysis for the determination of the polymers’ melting points and thermogravimetric analysis for the determination of the mass loss were performed. Fig. 3 reports the melting temperatures of all the synthesized polymers when the standard protocol (6h at 1000 mbar, 18 h at 20 mbar, 85 °C, 10% w w−1) was applied. It is possible to observe a general trend where an increase in polymer melting point aligns with increasing carbon chain length of the diester, where C4-based polymers have lower melting points than the C10-based polymers. This is due to the crystallinity of the C4-based polymers as discussed above. A similar increase is also observed when increasing the diol carbon chain length from C4 (BDO, blue) to C8 (ODO, green). In this case, increasing the dicarboxylic ester length from C4 to C8 reduces the melting point differences among the produced polymers, analogous to number average molecular weight observations plotted in Fig. 2.

In Table 2 we reported the % of Mn reduction for any diethyl ester chain in relation to the alkyl group in relation to 1,8-octanediol. As we can see from the collected data, the methyl ester (Me) (taken as 100%) is always the best performing one, followed by the diethyl (Et) and the dibutyl (Bu) ones. Also to notice that the diesters having methyl ester with the increase of the carbon chain length of the diester for the Bu end group are lower with the increase of the carbon chain length of the diester for the considered reaction.

Further to this, the difference in polymer melting temperature between the different diol chain lengths becomes less pronounced when increasing the diester chain length (Fig. 3).

The inert atmosphere (N2) thermogravimetric profile of the polymers presented in Fig. 4 is also consistent with the previously discussed molecular mass data. In fact, with the increase of the polymer’s Mn, and the increase of the diol’s carbon chain length (see Fig. 4a insert) the degradation temperature increases accordingly (Fig. 4a).

A comparison of the polymerisations conducted using the same diol (1,8-octanediol, ODO, C8) with three different diesters having methyl, ethanol or butanol alkyl groups on the monomers also show a remarkable difference in the obtained Mn, (see discussion above and Fig. 4b insert), with the dimethyl adipate-derived polyester proving more thermally stable than the diethyl equivalent, with this being more stable than the dibutyl. This indicates that the selection of the diester remains highly important for these transesterification reactions since the volatility of the leaving group proved to be a key point in determining the extent to the which the polyester chain grows. From the TGA profiles the temperatures at 5% and 50% mass loss (TD5 and TD50) were subsequently determined and are reported in Table S2 in ESI.

Rheology was used to further characterise the polymers and identify differences in their viscosity. Fig. 5 shows the viscosity change of the polymer melts based on a decrease of temperature for poly(1,6-hexylene adipate) synthesized from dimethyl adipate (blue), diethyl adipate (red) and dibutyl adipate (green). In all cases, viscosity steadily rose with decreasing temperature until the onset of freezing was reached, at which point viscosity increased rapidly. This further
exemplifies how the differing molecular weights (see Fig. 5 insert) lead
to different viscosity profiles. The shorter chain polymer behaves
remarkably different compared with the other two polymers with similar
Mw values. Comparative studies of the presented reactions in organic
media are needed in order to better elucidate the effect of viscosity on
the reaction progression. Moreover, we noted that the viscosity of any
initial mixture appeared to be below the lower detection limit (ca. <
0.2 Pa.s) of the apparatus when used under the same conditions.

The produced polyesters can find applications that range from the
biomedical field (as carriers in protein- and peptide-delivery systems)
[25] and, if further coupled with poly(ethylene glycol), for the pro-
duction of eco-friendly water-soluble polymers and coatings [26].

4. Conclusions

From the collected data we can conclude that CaLB is an effec-
tive catalyst for the synthesis of a range of aliphatic polyesters using a
solventless reaction system. Polyesters based on diesters with an
internal carbon chain length between 4 (succinate) and 10 (sebacate) and
diols with a carbon chain length between 4 (1,4-butanediol) and 8 (1,8-
 octanediol) were successfully synthesized via transesterification.
A strong effect of the selected alkyl group of the diester (dimethyl, diethyl
and dibutyl) was observed for all polyesters. Lower molecular weights
and monomer conversions were obtained using dibutyl esters since it
proved more difficult to remove the butanol by-product during the
reaction due to its higher boiling point (relative to methanol and
ethanol). DSC, TGA and rheology measurements confirm the trend
showing a large difference in degradation temperatures and viscosity of
the melts due to the polymers’ molecular weight. This work has set the
basis for efficient biocatalyzed syntheses of aliphatic polyesters having
Mn of ~6 and Mw of ~13 KDa and with monomers conversions > 94%.
This also represents the first systematic study of different dialkyl ali-
phatic diesters with various diols under identical reaction conditions.
