I. INTRODUCTION

Complex networks are characterized by a number of general properties that link together systems of very diverse origin, from nature, society, and technology [1–3]. The feature that has received most attention in the literature is the distribution of the number of neighbors of a node (degree), which is highly skewed, with a tail that can be often well approximated by a power law [4]. This property explains a number of striking skewed, with a tail that can be often well approximated by characteristics of complex networks, like their high resilience to random failures [5] and the very rapid dynamics of diffusion phenomena, like epidemic spreading [6]. The generally accepted mechanism yielding broad degree distributions is preferential attachment [7]: in a growing network, new nodes set links with existing nodes with a probability proportional to the degree of the latter. In this way the rate of accretion of neighbors will be higher for nodes with more connections, and the final degrees will be distributed according to a power law. This basic mechanism, however, taken alone without considering additional growing rules, generates networks with very low values of the clustering coefficient, a relevant feature of real networks [8]. Furthermore, these networks have no community structure [9,10] either.

High clustering coefficients imply a high proportion of triads (triangles) in the network. It has been pointed out that there is a close relationship between a high density of triads and the existence of community structure, especially in social networks, where the density of triads is remarkably high [11–15]. Indeed, if we stick to the usual concept of communities as subgraphs with an appreciably higher density of (internal) links than in the whole graph, one would expect that triads are formed more frequently between nodes of the same group than between nodes of different groups [16]. This concept has been actually used to implement well-known community finding methods [17,18]. Foster et al. [15] have studied equilibrium graph ensembles obtained by rewiring links of several real networks so as to preserve their degree sequences and introduce tunable values of the average clustering coefficient and degree assortativity. They found that the modularity of the resulting networks is the more pronounced, the larger the value of the clustering coefficient. Correlation, however, does not imply causation, and the work does not provide a dynamic mechanism explaining the emergence of high clustering and community structure.

Triadic closure [19] is a strong candidate mechanism for the creation of links in networks, especially social networks. Acquaintances are frequently made via intermediate individuals who know both us and the new friends. Besides, this process has the additional advantage of not depending on the features of the nodes that get attached. With preferential attachment, it is the node’s degree that determines the probability of linking, implying that each new node knows this information about all other nodes, which is not realistic. Instead, triadic closure induces an effective preferential attachment: getting linked to a neighbor A of a node corresponds to choosing A with a probability increasing with the degree $k_A$ of that node, according to a linear or sublinear preferential attachment. This principle is at the basis of several generative network models [13,20–30], all yielding graphs with fat-tailed degree distributions and high clustering coefficients, as desired. Toivonen et al. have found that community structure emerges as well [13].

Here we propose a systematic analysis of models based on triadic closure, and demonstrate that this basic mechanism can indeed endow the resulting graphs with all basic properties of real networks, including a significant community structure. These models can include or not an explicit preferential attachment, they can even be temporal networks, but as long as triadic closure is included, the networks are sufficiently sparse, and the growth is random, a significant community structure spontaneously emerges in the networks. In fact the nodes of these networks are not assigned any a priori hidden
variable that correlates with the community structure of the networks.

We will first discuss a basic model including triadic closure but not an explicit preferential attachment mechanism and we will characterize the community formation and evolution as a function of the main variables of the linking mechanism, i.e., the relative importance of closing a triad versus random attachment and the average degree of the graph. We find that communities emerge when there is a high propensity for triadic closure and when the network is sufficiently sparse (low average degree). We will also consider further models existing in the literature and including triadic closure, and we show that results concerning the emergence of the community structure are qualitatively the same, independently of the presence or not of the explicit preferential attachment mechanism or of the temporal dynamics of the links. Finally, we will introduce a variant of the basic model, in which nodes have a fitness and a propensity to attract new links depending on their fitness. Here clusters are less pronounced and, when the fitness is high, the function 

\[ P \] 

or to other randomly chosen nodes with probability 

\[ p \] 

are attached to neighbors of 

\[ i \] 

already. A total of 

\[ m \] 

edges are added, 

\[ 1 \] 

initial random edge and 

\[ m-1 \] 

involving triadic closure or random attachment.

In Fig. 1 the attachment mechanism of the model is schematically illustrated.

For simplicity we discuss here the case 

\[ m=2 \] 

. In the basic model the probability that a node 

\[ i \] 

acquires a new link at time 

\[ t \] 

given by

\[ \frac{1}{t} \left( 2 - p \right) + p \sum_{j} \frac{a_{ij}}{k_j} \] 

(4)

In an uncorrelated network, where the probability 

\[ p_{ij} \] 

that a node 

\[ i \] 

is connected to a node 

\[ j \] 

is 

\[ p_{ij} = \frac{k_i k_j}{\sum k_j} \] 

(\( n \) being the number of nodes of the network), we might expect that the proximity bias always induces a linear preferential attachment, i.e.,

\[ \sum_{j} \frac{a_{ij}}{k_j} \propto k_i, \] 

(5)

but for a correlated network this guess might not be correct. Therefore, assuming, as supported by the simulation results (see Fig. 2), that the proximity bias induces a linear or sublinear preferential attachment, i.e.,

\[ \Theta_i = p \sum_{j} \frac{a_{ij}}{k_j} \propto c k_i^\theta, \] 

(6)

with \( \theta = \theta(p) \leq 1 \) and \( c = c(p) \), we can write the master equation [31] for the average number 

\[ n_k(t) \] 

of nodes of degree 

\[ k \] 

at time 

\[ t \] 
.

From the simulation results it is found that the function \( \theta(p) \) is an increasing function of \( p \) for 

\[ m=2 \] 
.

Moreover the exponent \( \theta \) is also an increasing function of the number of edges of the new node 

\[ m \] 
.

Assuming the scaling in Eq. (6), the master equation for 

\[ m=2 \] 

reads

\[ n_k(t+1) = n_k(t) + \frac{2 - p + c(k-1)^\theta}{t} n_{k-1}(t)(1 - \delta_{k,2}) - \frac{2 - p + c k^\theta}{t} n_k(t) + \delta_{k,2}. \] 

(7)

In the limit of large values of \( t \), we assume that the degree distribution \( P(k) \) can be found as 

\[ \frac{n_k}{t} \to P(k). \]

So we find...
The figure is obtained by performing 100 realizations of networks of size $n = 100000$. The scaling allows us to define the exponents $\theta = \theta(p)$ defined by Eq. (6). The solution for $\theta = \theta(p)$ is given by

$$P(k) = C \frac{1}{3 - p + ck^\theta} \prod_{j=1}^{k-1} \left(1 - \frac{1}{3 - p + cj^\theta}\right),$$

where $C$ is a normalization factor. This expression can be approximated in the continuous limit by

$$P(k) \simeq D \frac{1}{3 - p + ck^\theta} e^{-(k-1)G(k-1, \theta, c)},$$

where $D$ is the normalization constant and $G(k, \theta, c)$ is given by

$$G(k, \theta, c) = -\theta z F_1 \left( \frac{1}{\theta}, 1 + \frac{1}{\theta}, -\frac{ck^\theta}{3 - p} \right) + \theta z F_1 \left( \frac{1}{\theta}, 1 + \frac{1}{\theta}, -\frac{ck^\theta}{2 - p} \right) + \ln \left(1 - \frac{1}{3 - p + ck^\theta}\right).$$

In this case the distribution is broad but not power law. For $\theta = 1$, instead, the distribution can be approximated in the continuous limit by a power law, given by

$$P(k) \simeq D \frac{1}{(3 - p + ck^\theta)^{\xi+1}},$$

where $D$ is a normalization constant. Therefore we find that the network is scale-free only for $\theta = 1$, i.e., only in the absence of degree correlations. In order to confirm the result of our theory, we have extracted from the simulation results the values of the exponents $\theta = \theta(p)$ as a function of $p$. With these values of the exponents $\theta = \theta(p)$, which turn out to be all smaller than 1, we have evaluated the theoretically expected degree distribution $P(k)$ given by Eq. (9) and we have compared it with simulations (see Fig. 3), finding optimal agreement.

We remark that this model has been already studied in independent papers by Vazquez [22] and Jackson and Rogers [24], who claimed that the model always yields power law degree distributions. Our derivation for $m = 2$ shows that this is not correct, in general, and in particular it is not correct when the growing network exhibits degree correlations, in which case we do not expect that the probability of reaching a node of degree $k_A$ by following a link is proportional to $k_A$. When the network is correlated we always find $\theta < 1$, i.e., the effective link probability is sublinear in the degree of the target node. We note, however, that the duplication model [25–28], in which every new node is attached to a random node and to each of its neighbors with probability $p$, displays at the same time degree correlations and power-law degree distribution.

We also find that the model spontaneously generates communities during the evolution of the system. To quantify how pronounced communities are, we use a measure called embeddedness, which estimates how strongly nodes are attached to their own cluster. Embeddedness, which we shall indicate with $\xi$, is defined as follows:

$$\xi = \frac{1}{n_c} \sum_c \frac{k_{in}^c}{k_{tot}^c},$$

where $k_{in}^c$ and $k_{tot}^c$ are the internal and the total degrees of community $c$ and the sum runs over all $n_c$ communities of the network. If the community structure is strong, most of the neighbors of each node in a cluster will be nodes of that cluster, so $k_{in}^c$ will be close to $k_{tot}^c$ and $\xi$ turns out to be close to 1; if there is no community structure $\xi$ is close to zero. However, one could still get values of embeddedness which are not too small, even in random graphs, which have no modular structure, as $k_{in}^c$ might still be sizable there. To eliminate such borderline cases, we introduce an additional variable, the node-based embeddedness, which we shall indicate with $\xi_n$. It is based on...
the idea that for a node to be properly assigned to a cluster, it must have more neighbors in that cluster than in any of the others. This leads to the following definition:

$$\xi_n = \frac{1}{n} \sum_i k_{i,\text{in}} - \frac{k_{i,\text{ext}}^{\text{max}}}{k_i},$$  \hspace{1cm} (13)$$

where $k_{i,\text{in}}$ is the number of neighbors of node $i$ in its cluster, $k_{i,\text{ext}}^{\text{max}}$ is the maximum number of neighbors of $i$ in any other cluster, and $k_i$ is the total degree of $i$. The sum runs over all $n$ nodes of the graph. For a proper community assignment, the difference $k_{i,\text{in}} - k_{i,\text{ext}}^{\text{max}}$ is expected to be positive, negative if the node is misclassified. In a random graph, and for subgraphs of approximately the same size, $\xi_n$ would be around zero. In a set of disconnected cliques (a clique being a subgraph where all nodes are connected to each other), which is the paradigm of perfect community structure, $\xi_n$ would be 1.

In Fig. 4(a) we show a heat map for $\xi_n$ as a function of the two main variables of the model, the probability $p$ and the number of edges per node, $m$, which is half the average degree. Communities were detected with nonhierarchical INFOMAP [32] in all cases. Results obtained by applying the Louvain algorithm [33] (taking the most granular level to avoid artifacts caused by the resolution limit [34]) yield a consistent picture. All networks are grown until $n = 50\,000$ nodes. We see that large values of $\xi_n$ are associated with the bottom left portion of the diagram, corresponding to high values of the probability of triadic closure and to low values of degree. So a high density of triangles ensures the formation of clusters, provided the network is sufficiently sparse. In Fig. 4(b) we present an analogous heat map for the average clustering coefficient $C$, which is defined [8] as

$$C = \frac{1}{n} \sum_{i,j,k} a_{ij} a_{jk} a_{ki} / k_i (k_i - 1),$$ \hspace{1cm} (14)$$

where $a_{ij}$ is the element of the adjacency matrix of the graph and $k_i$ is again the degree of node $i$. Figure 4(b) confirms that $C$ is largest when $p$ is high and $m$ is low, as expected.

The mechanism of formation and evolution of communities is schematically illustrated in Fig. 5. When the first denser clumps of the network are formed [Fig. 5(a)] out of random fluctuations in the density of triangles, newly added nodes are more likely to close triads within the protoclusters than between them [Fig. 5(b)]. As more nodes and links are added, the protoclusters become larger and larger and their internal density of links becomes inhomogeneous, so there will be a selective triadic closure within the denser parts, which yields a separation into smaller clusters (c). This cycle of growing and splitting plays repeatedly throughout the evolution of the system.

In Fig. 6 we show the time evolution of the node-based embeddedness $\xi_n$ during the growth of the system, until 500 nodes are added to the network, $m = 2$. We consider the two extreme situations $p = 0$, corresponding to the absence of triadic closure, and $p = 1$, where both links close a triangle every time and there is no additional noise. In the first case (green line), after a transient, $\xi_n$ settles to a low value, with small fluctuations; in the case with pure triadic closure;
instead, the equilibrium value is much higher, indicating strong community structure, and fluctuations are modest. In contrast with the random case, we recognize a characteristic pattern, with $\xi_s$ increasing steadily and then suddenly dropping. The smooth increase of $\xi_n$ signals that the communities are growing, the rapid drop that a cluster splits into smaller pieces: in the inset such breakouts are indicated by arrows. Embeddedness drops when clusters break up because the internal degrees $k_{i,\text{in}}$ of the nodes of the fragments in Eq. (13) suddenly decrease, since some of the old internal neighbors belong to a different community, while the values of $k_{i,\text{ext}}^\text{max}$ are typically unaffected.

### III. PREFERENTIAL ATTACHMENT OR TEMPORAL NETWORK MODELS INCLUDING TRIADIC CLOSURE

The scenario depicted in Sec. II is not limited to the basic model we have investigated, but it is quite general. To show this, we consider here two other models based on triadic closure.

The model by Holme and Kim [20] is a variant of the Barabási-Albert model of preferential attachment (BA model) which generates scale-free networks with clustering. The new node joining the network sets a link with an existing node, chosen with a probability proportional to the degree of the latter, just as in the BA model. The other $m - 1$ links coming with the new node, however, are attached with a probability $P_t$ to a random neighbor of the node which received the most recent preferentially attached link, closing a triangle, and with a probability $1 - P_t$ to another node chosen with preferential attachment. By varying $P_t$ it is possible to tune the level of clustering in the network, while the degree distribution is the same as in the BA model, i.e., a power law with exponent $-3$, for any value of $P_t$. In Fig. 7 we show the same heat map as in Fig. 4 for this model, where we now report the probability $P_t$ on the y axis. Networks are again grown until $n = 50 000$ nodes. The picture is very similar to what we observe for the basic model.

![Fig. 7.](image7.png)

**FIG. 7.** (Color online) Heat map of node-based embeddedness (a) and average clustering coefficient (b) as functions of $P_t$ and $m$ for the model by Holme and Kim [20]. For each pair of parameter values we report the average over 50 network realizations. The white area in the upper right corresponds to systems where a single community, consisting of the whole network, is found, which is not interesting. The diagrams look qualitatively similar to that of the basic model (Fig. 4), with highest embeddedness and clustering coefficient in the lower left region.

The model by Marsili et al. [23], at variance with most models of network formation, is not based on a growth process. The model is a model for temporal networks [35], in which the links are created and destroyed on a fast time scale while the number of nodes remains constant. The starting point is a random graph with $n$ nodes. Then three processes take place, at different rates:

(1) any existing link vanishes (rate $\lambda$);

(2) a new link is created between a pair of nodes, chosen at random (rate $\eta$);

(3) a triangle is formed by joining a node with a random neighbor of one of his neighbors, chosen at random (rate $\xi_M$).

In our simulations we start from a random network of $n = 50 000$ nodes with average degree 10. The three rates $\lambda$, $\eta$, and $\xi_M$ can be reduced to two independent parameters, since what counts is their relative size. The number of links deleted at each iteration is proportional to $\lambda M$, where $M$ is the number of links of the network, while the numbers of links created via the two other processes are proportional to $\eta n$ and $\xi_M n^2$, respectively. The number of links $M$ varies in time but in order to get a nontrivial stationary state, one should reach an equilibrium situation where the numbers of deleted and created links match. A variety of scenarios are possible, depending on the choices of the parameters. For instance, if $\xi_M$ is set equal to zero, there are no triads, and what one gets at stationarity is a random graph with average degree $2n/\lambda$. So, if $\eta \ll \lambda$, the graph is fragmented into many small connected components. In one introduces triadic closure, the clustering coefficient grows with $\xi_M$ if the network is fragmented, as triangles concentrate in the connected components. Moreover the model can display a veritable first-order phase transition and in a region of the phase diagram displays two stable phases: one corresponding to a connected network with large average clustering coefficient and the other one corresponding

![Fig. 8.](image8.png)

**FIG. 8.** (Color online) Heat map of node-based embeddedness (a) and average clustering coefficient (b) as functions of the rates $\lambda$ and $\xi_M$ for the model by Marsili et al. [23] ($\eta = 1$). For each pair of parameter values we report the average over 50 network realizations. The white area in the upper right corresponds to systems where a single community, consisting of the whole network, is found, which is not interesting. These diagrams have better communities (higher embeddedness and clustering coefficient) towards the upper right, unlike those in Figs. 4 and 7, because of the different meaning and effect of the parameters. However, there is a strong correspondence between high clustering coefficient and strong community structure, as in the other models.
to a disconnected network. Interestingly, if there is a dense single component, the clustering coefficient decreases with $\xi_M$. The degree distribution can follow different patterns too: it is Poissonian in the diluted phase, where the system is fragmented, and broad in the dense phase, where the system consists of a single component with an appreciable density of links. In Fig. 8 we show the analogous heat map as in Figs. 4 and 7, for the two parameters $\lambda$ and $\xi_M$. The third parameter $\eta = 1$. We consider only configurations where the giant component covers more than one-half of the nodes of the network. The diagrams are now different because of the different role of the parameters, but the picture is consistent nevertheless. The clustering coefficient $C$ is highest when the ratio of $\lambda$ and $\xi_M$ lies within a narrow range, yielding a sparse network with a giant component having a high density of triangles and a corresponding presence of strong communities.

IV. THE BASIC MODEL INCLUDING TRIADIC CLOSURE AND FITNESS OF THE NODES

In this section we introduce a variant of the basic model, where the link attractiveness depends on some intrinsic fitness of the nodes. We will assume that the nodes are not all equal and assign to each node $i$ a fitness $\eta_i$ representing the ability of a node to attract new links. We have chosen to parametrize the fitness with a parameter $\beta > 0$ by setting

$$\eta_i = e^{-\beta \epsilon_i},$$

with $\epsilon$ chosen from a distribution $g(\epsilon)$ and $\beta$ representing a tuning parameter of the model. We take

$$g(\epsilon) = (1 + \nu)e^{\nu},$$

with $\epsilon \in (0,1)$. When $\beta = 0$ all the fitness values are the same; when $\beta$ is large small differences in the $\epsilon_i$ cause large differences in fitness. For simplicity we assume that the fitness values are quenched variables assigned once for all to the nodes. As in the basic model without fitness, the starting point is a small connected network of $n_0$ nodes and $m_0 \geq m$ links. The model contains two ingredients:

- **Growth.** At time $t$ a new node is added to the network with $m \geq 2$ links.
- **Proximity and fitness bias.** The probability of attaching the new node to node $i_1$ depends on the order in which links are added.

The first link of the new node is attached to a random node $i_1$ of the network with probability proportional to its fitness. The probability that the new node is attached to node $i_1$ is then given by

$$\Pi[0](i_1) = \frac{\eta_{i_1}}{\sum_j \eta_j}.$$

For $m = 2$ the second link is attached to a node of the network chosen according to its fitness, as above, with probability $1 - p$, while with probability $p$ it is attached to a node chosen randomly between the neighbors of the node $i_1$ with probability proportional to its fitness. Therefore in the first case the probability of attaching to a node $i_2 \neq i_1$ is given by

$$\Pi[0](i_2) = \frac{\eta_{i_2} (1 - \delta_{i_1,i_2})}{\sum_{j \neq i_1, i_2} \eta_j},$$

with $\delta_{i_1,i_2}$ indicating the Kronecker delta, while in the second case the probability $\Pi[1](i_2)$ that the new node links to node $i_2$ is given by

$$\Pi[1](i_2) = \frac{\eta_{i_2} \alpha_{i_1,i_2}}{\sum_j \eta_j \alpha_{i_1,j}},$$

where $\alpha_{ij}$ indicates the matrix element $(i, j)$ of the adjacency matrix of the network.

FIG. 9. (Color online) Degree distribution of the model with fitness, for three values of the parameter $\beta$, which indicates the heterogeneity of the distribution of the fitness of the nodes. Symbols stand for the results obtained by building the network via simulations, continuous lines of our analytical derivations. The figure is obtained by performing 100 realizations of networks of size $n = 100 000$ with $\nu = 6$.

FIG. 10. (Color online) Heat map of node-based embeddedness (a) and average clustering coefficient (b) as functions of the probability of triadic closure $p$ and the heterogeneity parameter $\beta$ of the fitness distribution of the nodes, for the model with fitness. The number of new edges per node is $m = 2$. For each pair of parameter values we report the average over 50 network realizations. When $\beta = 0$ we recover the basic model, without fitness. We see the highest values of embeddedness in the lower left, while highest values of the clustering coefficient are in the lower right. When $\beta$ increases, we see a drastic change of structure in contrast to the previous pattern: communities disappear, whereas the clustering coefficient gets higher.
Further edges. For $m > 2$, further edges are added according to the “second link” rule in the previous point. With probability $p$ an edge is added to a neighbor of the first node $i_1$, not already attached to the new node, according to the fitness rule. With probability $1 - p$, a link is set to any node in the network, not already attached to the new node, according to the fitness rule.

For simplicity we shall consider here the case $m = 2$. The probability that a node $i$ acquires a new link at time $t$ is given by

$$e^{-\beta t} \left[ (2 - p) + p \sum_j \frac{a_{ij}}{\sum_r a_{jr}} \right].$$

Similarly to the case without fitness, here we will assume, supported by simulations, that

$$\Theta_i = p \sum_j \frac{\eta_i a_{ij}}{\sum_r \eta_r a_{jr}} \approx c_k \theta^{(\epsilon)},$$

where, for every value of $p$, $\theta = \theta(\epsilon) \leq 1$ and $c = c(\epsilon)$.

We can write the master equation for the average number $n_{k,\epsilon}(t)$ of nodes of degree $k$ and energy $\epsilon$ at time $t$ as

$$n_{k,\epsilon}(t + 1) = n_{k,\epsilon}(t) + e^{-\beta t} \frac{[2 - p + c(\epsilon)(k - 1)^\theta]}{t} n_{k-1,\epsilon}(t)(1 - \delta_{k,2})$$

$$- e^{-\beta t} \frac{[2 - p + c(\epsilon)k^{\theta(\epsilon)}]}{t} n_{k,\epsilon}(t) + \delta_{k,2} g(\epsilon).$$

(22)

In the limit of large values of $t$ we assume that $n_{k,\epsilon}/t \to P^*(k)$, and therefore we find that the solution for $P^*(k)$ is given by

$$P^*(k) = C(\epsilon) \frac{1}{1 + e^{-\beta t} \frac{[2 - p + c(\epsilon)k^{\theta(\epsilon)}]^{-1}}{t} \prod_{j=1}^{k-1} \frac{1}{1 + e^{-\beta t} \frac{[2 - p + c(\epsilon)j^{\theta(\epsilon)}]^{-1}}{t}}}.$$

(23)

where $C(\epsilon)$ is the normalization factor. This expression for $\theta(\epsilon) < 1$ can be approximated in the continuous limit by

$$P^*(k) \approx D(\epsilon) \frac{1}{1 + e^{-\beta t} \frac{[2 - p + c(\epsilon)k^{\theta(\epsilon)}]^{-1}}{t}}.$$

(24)

where $D(\epsilon)$ is the normalization constant, and $G(k,\epsilon,\theta,c)$ is given by

$$G(k,\epsilon,\theta,c) = -\theta_2 F_1 \left( \frac{1}{\theta}, 1 + \frac{1}{\theta}, \frac{c k^{\theta}}{2 - p + e^{t \theta}} \right)$$

$$+ \theta_2 F_1 \left( \frac{1}{\theta}, 1 + \frac{1}{\theta}, \frac{c k^{\theta}}{2 - p} \right)$$

$$+ \ln \left( 1 - \frac{1}{1 + e^{t \theta} / (c k^{\theta}} \right).$$

(25)
When $\theta(\epsilon) = 1$, instead, we can approximate $P^* (k)$ with a power law, i.e.,
\[ P^* (k) \simeq D(\epsilon) [1 + e^{\beta \epsilon (2 - p + c(\epsilon) k)}]^{-e^{\beta \epsilon / c(\epsilon) - 1}}. \] (26)

Therefore, the degree distribution $P(k)$ of the entire network is a convolution of the degree distributions $P^* (k)$ conditioned on the value of $\epsilon$, i.e.,
\[ P(k) = \int d\epsilon P^* (k). \] (27)

As a result of this expression, we found that the degree distribution can be a power law also if the network exhibits degree correlations and $\theta(\epsilon) < 1$ for every value of $\epsilon$. Moreover we observe that for large values of the parameter $\beta$ the distribution becomes broader and broader until a condensation transition occurs at $\beta = \beta_c$, with the value of $\beta_c$ depending on both the parameters $\nu$ and $p$ of the model. For $\beta > \beta_c$, successive nodes with maximum fitness (minimum value of $\epsilon$) become “superhubs,” attracting a finite fraction of all the links, similarly to what happens in Ref. [36]. In Fig. 9 we see the degree distribution of the model, obtained via numerical simulations, for different values of $\beta$. The continuous lines, illustrating the theoretical behavior, are well aligned with the numerical results, as long as $\beta < \beta_c$.

In Fig. 10 we show the heat map of $\tilde{\xi}_n$ and $C$ for the model, as a function of the parameters $p$ and $\beta$. The number of edges per node is $m = 2$, and the networks consist of 50 000 nodes. Everywhere in this work, we set the parameter $\nu = 6$. For $\beta = 0$ all nodes have identical fitness and the model is reduced to the basic model. So we recover the previous results, with the emergence of communities for sufficiently large values of the probability of triadic closure $p$, following a large density of triangles in the system. The situation changes dramatically when $\beta$ starts to increase, as we witness a progressive weakening of community structure, while the clustering coefficient keeps growing, which appears counterintuitive. In the analogous
When $\beta$ is sufficiently large, communities disappear, despite the high density of triangles. To check what happens, we compute the probability distribution of the scaled link density $\tilde{\rho}$ and the node-based embeddedness $\xi_n$ of the communities of the networks obtained from 100 runs of the model, for three different values of $\beta$: 0, 6, and 20. All networks are grown to 100,000 nodes. The scaled link density $\tilde{\rho}$ of a cluster is defined as

$$\tilde{\rho} = \frac{2l_c}{n_c - 1},$$

where $l_c$ and $n_c$ are the number of internal links and of nodes of cluster $c$. If the cluster is treelike, $\tilde{\rho} \approx 2$, if it is cliquish $\tilde{\rho} \approx n_c$, so it grows linearly with the size of the cluster. The distributions of $\xi_n$ and $\tilde{\rho}$ are shown in Fig. 12. They are peaked, but the peaks undergo a rapid shift when $\beta$ goes from 0 to 20. The situation resembles what one usually observes in first-order phase transitions. The embeddedness ends up peaking at low values, quite distant from the maximum 1, while the scaled link density eventually peaks sharply at 2, indicating that the subgraphs are effectively treelike.

What kind of objects are we looking at? To answer this question, in Figs. 13 and 14 we display two pictures of networks obtained by the fitness model, for $\beta = 0$ and $\beta = 20$, respectively. The number of nodes is 2000, and the number of edges per node $m = 2$. The probability of triadic closure is $p = 0.97$, as we want a very favorable scenario for the emergence of structure. The subgraphs found by our community detection method (nonhierarchical INFOMAP, but the Louvain method yields a similar picture) are identified by the different colors. The insets show an enlarged picture of the subgraphs, which clarify the apparent puzzle delivered by the previous diagrams. For the basic model $\beta = 0$ (Fig. 13), the subgraphs are indeed communities, as they are cohesive objects which are only loosely connected to the rest of the graph. The situation remains similar for low values of $\beta$. However, for sufficiently high $\beta$ (Fig. 14), a phenomenon of link condensation takes place, with a few superhubs attracting most of the links of the network [36]. Most of the other nodes are organized in groups which are “shared” between pairs (for $m = 2$, or more generally $m$-ples) of superhubs (see Fig. 14). The community embeddedness is low because there are always many links flowing out of the subgraphs, towards superhubs. Besides, since the superhubs are all linked to each other, this generates high clustering coefficients for the subgraphs, as observed in Figs. 10 and 11. In fact, the clustering
Triadic closure is a fundamental mechanism of link formation, especially in social networks. We have shown that this mechanism alone is capable of generating systems with all the characteristic properties of complex networks, from fat-tailed degree distributions to high clustering coefficients and strong community structure. In particular, we have seen that communities emerge naturally via triadic closure, which tend to generate cohesive subgraphs around portions of the system that happen to have higher density of links, due to stochastic fluctuations. When clusters become sufficiently large, their internal structure exhibits in turn link density inhomogeneities, leading to a progressive differentiation and eventual separation into smaller clusters (separation in the sense that the density of links between the parts is appreciably lower than within them). This occurs both in the basic version of the network growth model based on triadic closure and in more complex variants. The strength of community structure is the higher, the sparser the network and the higher the probability of triadic closure.

We have also introduced a variant, in which link attractiveness depends on some intrinsic appeal of the nodes, or fitness. Here we have seen that, when the distribution of fitness is not too heterogeneous, community structure still emerges, although it is weaker than in the absence of fitness. By increasing the heterogeneity of the fitness distribution, instead, we observe a major change in the structural organization of the network: communities disappear and are replaced by special subgraphs, whose nodes are connected only to superhubs of the network, i.e., nodes attracting most of the links. This structural phase transition is associated with very high values of the clustering coefficient.
