A B S T R A C T

Emotional stimuli processing during childhood helps us to detect salient cues in our environment and prepares us for our social life. In early childhood, the emotional valences of auditory and visual input are salient and relevant cues of social aspects of the environment, and it is of special interest to understand how exactly the processing of emotional stimuli develops. Near-infrared spectroscopy (NIRS) is a non-invasive neuroimaging tool that has proven valuable in studying emotional processing in children. After conducting a systematic search of PubMed, Web of Science, and Embase databases, we examined 50 NIRS studies performed to study emotional stimuli processing in children in the first 2 years of age. We found that the majority of these studies are done in infants, and the most commonly used stimuli are visual and auditory. Many of the reviewed studies suggest the involvement of bilateral temporal areas in emotional processing of visual and auditory stimuli. It is unclear which neural activation patterns reflect maturation and at what age the emotional encoding reaches those typically seen in adults. Our review provides an overview of the database on emotional processing in children up to 2 years of age. Furthermore, it demonstrates the need to include the less-studied age range of 1 to 2 years, and suggests the use of combined audio-visual stimuli and longitudinal studies for future research on emotional processing in children. Thus, NIRS might be a vital tool to study the associations between the early pattern of neural responses and socioemotional development later in life.

Keywords: NIRS, Near-infrared spectroscopy, emotion, brain.

Introduction

Emotions direct our attention and motivate behavior and can be activated by internal or external stimuli. In addition to the primary sensory areas such as the occipital cortex and the auditory cortex, key brain areas involved in processing of emotional stimuli in adults include bilateral cortical structures, such as the orbitofrontal cortex, cingulate cortex, inferolateral parietal cortex, temporal cortex, amygdala and (para)hippocampus, and the prefrontal cortex. Additionally, key subcortical structures involved in the processing of emotional stimuli include the thalamus, hypothalamus, fornix, mamillary bodies, olfactory bulbs, hypothalamus, and basal ganglia. Emotional processing thus engages wide brain circuits in the adult brain but how they emerge during development is far from established.

Brain volume increases rapidly during the early years of life, reaching almost 75% of adult brain volume during the first 2 years of age. This process is coupled with rapid white matter development, mainly observed first through tissue growth and the progression of myelination that continues throughout childhood. The core of emotional brain circuits are likely formed during the early years of life, and this time of neuronal growth enables the crucial first steps of neural development that prepare an individual for social life. These processes are influenced by prenatal development and genetic factors as well as the postnatal environment. The emotion processing network is crucial in determining the significance of external stimuli and providing cues on how to respond in social situations, which has far-reaching implications for later development and health.

Emotional processing has been studied with various functional neuroimaging modalities such as electroencephalography (EEG), magnetoencephalography (MEG), functional magnetic resonance imaging (fMRI), and near-infrared spectroscopy (NIRS). NIRS is an imaging method that uses the absorption of red and near-infrared light (630 to 950 nm) by specific chromophores to measure the hemodynamics of a tissue of interest. The measurements done with NIRS are based on neurovascular coupling. In response to a local increase in

neuronal activation, a temporally and spatially coincident increase in oxygen metabolism is thought to exist, causing an initial decrease in oxygenated hemoglobin (HbO$_2$) and an increase in deoxygenated hemoglobin (HbR). Following this, arterial dilation ensues as well as a local increase in cerebral blood flow (CBF) and cerebral blood volume (CBV). As oxygen-rich arterial blood flows into the region, total hemoglobin (HbT) and HbO$_2$ concentrations typically increase and HbR decreases within several seconds. Changes in the concentration of HbO$_2$ and HbR result in changes in the intensity of the reflected NIR light. Thus, HbO$_2$, HbR, and HbT are the most often used NIRS metrics (Fig 1).

At the practical level, during an NIRS measurement, the light is projected into the scalp at the source position, after which the photons migrate through the tissue in random trajectories due to multiple scattering and photons change their direction of propagation as a result of interacting with tissues. During absorption, the energy of a photon is absorbed by the tissue and converted into a small amount of thermal energy. After interacting with the tissue components in the vicinity of the NIR light source, the photons that are not absorbed in the process exit the tissue. Light detectors that are at a distance of a few centimeters from the source position detect part of this light. The surface of the scalp that is not directly under sources or detectors should be covered by black absorptive material to avoid influence from external light and to prevent direct transmission of light between source and detector.

NIRS does not require restriction of movements of the child and the mother can hold the child during the measurement (Fig 2), which is advantageous in pediatric neuroimaging. NIRS has a relatively good temporal resolution and most systems can measure several samples per second, which makes it possible to observe changes in the time course of the hemodynamic response as well as differences in response latency between brain regions (Fig 3). However, a few of the disadvantages of NIRS include a temporal delay in hemodynamic response, limited depth resolution, and interference from hair (that is more pronounced with participants having dark hair color). Table 1 provides a comparison of NIRS with fMRI, EEG, and MEG for studies in children.

In this paper, we report a critical review of current literature on emotional processing studies using NIRS in infants and children up to 2 years of age. We discuss the implications of these studies, methodological limitations, and future prospects of research on emotional processing using NIRS.

The Systematic Review (Methods)
We conducted a systematic search across the databases PUBMED, WEB of SCIENCE, and EMBASE (from inception
through January 8, 2018) to identify all the NIRS studies using emotional stimuli as external sensory stimuli in infants and children up to 2 years of age. The search strategy combined the following medical subject headings (MeSH) terms and keywords: (NIRS OR fNIRS) AND (infants OR newborns OR children) AND (brain OR neuroimaging). This resulted in 708 articles in PUBMED, 699 articles in the WEB of SCIENCE, and 1,099 articles in EMBASE.

After screening for duplicates, the remaining studies (n = 836) were filtered by reading the titles and abstracts to search for the studies that addressed emotional processing using emotionally relevant sensory stimuli. The exclusion criteria were: (1) written in languages other than English; (2) carried out in nonhuman species; (3) subjects were adults or children older than 2 years of age; and (4) did not address emotional processing. This resulted in the exclusion of 758 articles. Additionally, we included articles that were identified from reference lists of the relevant articles (n = 22).

Next, we went through the full text of the 100 articles and specifically included only those publications that addressed emotional processing by using emotionally relevant sensory stimuli, as emotional responses can be induced by external sensory stimuli.16 Publications were excluded if they did not include original data (eg, reviews, commentaries) or if they were not published as a full-length article in a peer-reviewed journal (eg, abstracts for presentations, case reports). This resulted in 50 articles for this review. The selected articles were then reviewed in detail, and the relevant data were extracted, and the main findings were reported. Figure 4 shows the preferred reporting items for systematic reviews and meta-analyses (PRISMA) flow diagram for summarizing this review process.

We did not focus on experimental design considerations in between the studies, which has been covered elsewhere.17 After conducting the review, we planned to carry out a meta-analysis on each of the topics, but we found out that it was not plausible...
due to the differences in the equipment used, measurement areas, and experimental design.

Overview of NIRS Studies on Emotional Processing in Children up to 2 Years of Age

Emotionally Relevant Visual Stimuli

Infants likely start to recognize the identity of a face, irrespective of its orientation, at a developmental period between 5 and 8 months of age.\textsuperscript{18,19} The right temporal cortex has been implicated in face detection during infancy.\textsuperscript{20–23} Left temporal cortical activation has also been reported for processing of face-like objects in 7- to 8-month-old infants.\textsuperscript{24} Kobayashi et al additionally reported a neural adaptation effect (observed by attenuation in brain responses) for the repeated measurement of the same face as compared to different faces in infancy.\textsuperscript{23,25} Furthermore, there appears to be an increased sensitivity toward adult faces in infancy.\textsuperscript{26} Right temporal areas are seen to be activated in infants in response to adult faces (and not infant faces).\textsuperscript{27}

The caretaker’s face is one of the most frequently occurring visual stimuli during infancy and thus most likely carries early social and emotional valence. Right frontotemporal cortex activation has been observed in 6-9-month-old infants in response to their mothers’ faces as compared to unknown faces.\textsuperscript{28} Their mothers’ faces (in contrast to unfamiliar faces) have been determined to cause left temporal activation in 7- to 8-month-old infants.\textsuperscript{29} Right frontal (most likely orbitofrontal cortex) activation has been noted in 7-month-old infants in response to smiling soundless videos of their mothers (as compared to neutral expression).\textsuperscript{30} Infants can discriminate between the smiles of their own mothers and the smiles of unfamiliar mothers. Medial prefrontal activation (around the anterior orbitofrontal cortex) has been observed in 9-13-month-old infants on viewing movies of their own mothers’ smiles (as compared to viewing unfamiliar mothers’ smiles).\textsuperscript{31} Thus, the frontal cortex likely plays a significant role in the recognition of social positive affect in infancy.

Happy faces are seen to cause activation in the left temporal areas (as compared to baseline), while angry faces seem to activate right temporal areas in 7- to 8-month-old infants.\textsuperscript{32} Bilateral temporal cortices have been implicated in the processing of social dynamic stimuli (as compared to nonsocial dynamic stimuli) in infants.\textsuperscript{33,34} Additionally, infant temperament traits appear to

---

**Fig 4.** Preferred reporting items for systematic reviews and meta-analyses (PRISMA) flow diagram for summarizing the review process. EMBASE = Excerpta Medica database.
modulate how infants respond to emotional visual stimuli. The right posterior temporal region activation has been reported by Kant et al in response to social compared to non-social dynamic stimuli in 5-month-old infants. Furthermore, this differential activation was smaller in infants who show higher negative affect. These results suggest that decreased cortical sensitivity to social stimuli in infants showing high negative affect may be an early biomarker for later difficulties in social interaction. Increased left prefrontal cortex activation has been observed in response to happy faces in 7-month-old infants with low negative emotionality temperament [as compared to infants with high negative emotionality temperament]. As temperamental one of the earliest observable features of personality and among the major determinants of interaction between the children and their caretakers, early brain responses to emotional cues in the environment may be interesting biomarkers for later development, which makes studies combining these metrics especially valuable.

Thus, bilateral temporal cortices and the frontal cortex are implicated in processing emotional visual stimuli in children up to 2 years of age. However, the probe position limits the brain region that can be studied, and the neural circuits of visual recognition are still developing in infancy. It is evident that the developmental pathways and possible shifts in lateralization patterns can only be delineated in future longitudinal studies. Table 2 provides a detailed summary of the reviewed NIRS studies on visual emotional processing in children up to 2 years of age.

Emotionally Relevant Auditory Stimuli

Processing of emotional auditory cues seems to be already present at birth. Emotional prosody refers to communicating feelings using different elements of speech such as syllable length, loudness, and voice pitch. Zhang et al reported right temporal cortex [mainly the middle temporal gyrus and superior temporal gyrus] activation in response to emotional, relative to neutral, prosody in neonates as early as 2–8 days after birth. Furthermore, the researchers observed a right parietal area (approximately located in the supramarginal gyrus) that showed a heightened sensitivity to fearful, relative to happy and neutral, prosody.

Native language is usually the predominant way in which caregivers communicate with infants. Sato et al reported left temporal-parietal activation in response to forward maternal language in contrast to backward maternal language or forward speech in a foreign language. Minagawa-Kawai et al observed left-lateralized responses to native speech [as compared to non-native speech] in 4-month-old infants. Furthermore, they observed significant activation in response to emotional voices, i.e., human vocalizations with no linguistic content, either with a positive (e.g., admiration and laughing) or negative emotional valence (e.g., crying and sigh) in right temporal areas of infants. Human voice [as compared to nonvoice sounds] causes activation in the voice-selective regions of the bilateral temporal cortices in infants between 4 and 7 months of age. Infant-directed speech (IDS) might be one of the first sounds to elicit emotional responses in infants. Bilateral frontotemporal, frontal, temporal, and temporoparietal regions are seen to be activated by IDS [as compared to reverse speech or silence] in infants. IDSs from infants’ own mothers (rather than from unfamiliar mothers) are seen to cause frontal activation in infants. Dorsal medial prefrontal cortex activation has been observed in 6-month-old infants in response to hearing their own names (as compared to other names), especially when spoken by their mother, as compared to a stranger’s voice. While the infants’ mothers’ voices activated the left frontal area [more than right], their female nurse’s voice activated the right frontal area [more than left]. Thus, talker familiarity seems to affect speech processing and activates putative future brain regions of emotional processing in infants.

Emotions differentially modulate voice processing in infants. Grossmann et al reported activation in the bilateral superior temporal cortex in response to human voices as compared to nonvocal sounds in 7-month-old (but not 4-month-old infants), thereby, suggesting that voice-sensitive brain encoding appears between 4 and 7 months of age. Furthermore, hearing emotional prosody words (happy and angry), but not neutral prosody, caused activation in the right temporal cortex, and hearing angry prosody caused more activation in the right temporal cortex than happy prosody. Such a neural mechanism is thought to prioritize threat-related emotional stimuli and act as a protective mechanism. Listening to happy speech (but not angry or neutral) caused activation in the right inferior frontal cortex of 7-month-old infants. Thus, right temporal cortex seems to be involved in processing angry and happy [angry > happy] words, while right inferior frontal cortex is implicated in processing happy words.

Overall, bilateral frontotemporal, frontal, temporal, temporoparietal, and parietal regions have been implicated in processing emotional auditory stimuli in children up to 2 years of age. Table 3 provides a detailed summary of the reviewed NIRS studies on auditory emotional processing in children up to 2 years of age.

Emotionally Relevant Audiovisual Stimuli

Audiovisual emotional stimuli expectedly engage brain regions implicated in studies using either auditory or visual emotional stimuli. Occipital and bilateral temporal activation has been reported by Borfeldt et al in response to auditory stimuli [IDS with positive affective tone and animated objects]. Whereas occipital activation has been noted in response to visual-only stimuli [animated objects such as spirals, circles, and rectangles] in infants. Using the same stimuli, greater activation was observed in the left temporal cortex [as compared to the right temporal cortex] in response to audiovisual stimuli as compared to visual-only stimuli in infants. Dorosmedial prefrontal cortical activation has been observed in response to the socially interactive game, “peek-a-boo,” in which both visual [direct gaze] and auditory [IDS] stimuli were presented with an adult’s direct gaze compared to an averted gaze. These studies highlight the role of bilateral temporal cortices, prefrontal cortex, and occipital areas in processing audiovisual stimuli in children.

Cortical responses to social cues were reported by Lloyd-Fox et al across participants ranging in age from newborn to toddlerhood. The researchers reported that infants at 0–2 months of age exhibited nonsocial auditory selectivity, an effect that persists until 4–8 months when there is a transition to greater social stimulus selectivity. Thereafter, 9- to 24-months of age infants showed socially selective brain responses to both the visual and auditory stimuli. Fava et al reported that younger infants [3–6-month old] showed a greater overall response to...

Interestingly, Miguel et al oxygenated hemoglobin; HbR: deoxygenated hemoglobin; HbT: total hemoglobin

Although, some studies report no significant response to painful stimuli such as venipuncture or heel lance in infants.

tex activation as compared to nonaffective touch in 2-month-old valence (affective touch) causes temporal cortex and insular cortex lateral anterior prefrontal cortices in 10-month-old infants, but not in 3- or 6-month-old infants.

Thus, it seems that STS-TPJ area is already specialized in children older than 1 year of age for processing social cues from the environment. Table 4 provides a detailed summary of the reviewed NIRS studies on emotional processing using audiovisual stimuli in children up to 2 years of age.

Emotionally Relevant Olfactory, Tactile, and Noxious Stimuli

Maternal breast milk odor has been noted to cause activation in the orbitofrontal cortex and left prefrontal cortex in newborns. Jönsson et al reported that touch with emotional valence (affective touch) causes temporal cortex and insular cortex activation as compared to nonaffective touch in 2-month-old infants. Affective touch is seen to cause activation in the bilateral anterior prefrontal cortices in 10-month-old infants, but not in 3- or 6-month-old infants.

Interestingly, Miguel et al observed somatosensory activation to both affective and discriminative touch, but no activation to these stimuli in temporal regions/pSTS in 7-month-old infants. Therefore, the authors suggest that 7-month-old infants do not yet recruit socioemotional brain areas in response to affective touch.

Somatosensory cortices activation has been noted in response to painful stimuli such as venipuncture or heel lance in infants. Although, some studies report no significant differences in cortical responses during painful stimuli in neonates by prior breastfeeding and sucrose administration. However, recent studies show that skin-to-skin contact with their mothers reduces contralateral somatosensory activation during venipuncture in premature infants. This implies that skin-to-skin contact is an easy method by which parents can also get more involved in their infants’ care and pain management.

Recent studies link aberrant emotional processing has been linked to developmental disorders with impairments in social interaction and communication such as autism spectrum disorder (ASD). Table 4 provides a detailed summary of the reviewed NIRS studies using the olfactory, tactile, and noxious stimuli for investigating emotional processing in children up to 2 years of age.

Methodological Considerations and Limitations

Most of the NIRS studies on emotional processing in children have been done in infants, and visual and auditory stimuli are the most commonly used stimuli. However, there are few studies done in children 1 to 2 years of age. This challenging age group can provide an interesting window to study how emotional circuits are formed in the early years of life and enable us to be social entities later on. Thus, there is a need for further studies on emotional processing in toddlers, and NIRS can prove to be an important tool in this pursuit. Future studies should consider the possibility of combining auditory and visual stimuli and the inclusion of the less-studied stimuli (such as touch, pain, and olfactory). This might prove fruitful because, in the real world, we are usually exposed to stimuli from two or more sensory modalities simultaneously.

However, like any other method, there are several limitations with NIRS as well. The NIRS signal integrates a volume of tissue that is not precisely known, given the uncertainties in the optical properties of the underlying tissue. Other difficulties with functional NIRS studies include the effect of background physiology, sleep state, and artifacts due to motion and hair (especially with dark hair). NIRS outcome is variable due to its sensitivity to movement, limited sensitivity to deeper areas of the brain, and difficulties in dealing with the effects of scalp circulation. Additionally, in terms of studying task-related responses, the background physiology can be considered an artifact, which makes the analysis more complicated. Due to thin scalps and relatively high partial volume of the brain in fNIRS measurements of infants and small children, the proportion of unwanted baseline physiology originating in nonbrain tissue in the signal is smaller than in the adult fNIRS studies. Motion artifacts are common in 3-12-month-old infants, but in newborns, the child typically sleeps most of the time and motion artifacts leading to data exclusion are less common.

When doing task-related hemodynamic studies, the resting state hemodynamics can confound the results, and a few precautions are needed to get accurate task-related responses. First, the timing of the stimulus presentation should be randomized to avoid the subject anticipating the stimulus and to avoid possible phase-locking of the resting state hemodynamics to the stimulus presentation. Second, the number of repetitions of the stimulus should be large enough to obtain statistical significance for the difference between stimulus conditions.

(Continued)
Moreover, several recent studies have shown certain problematic aspects with NIRS measurements, such as systemic artifacts or the differential pathlength factors (DPFs). DPF can be measured using time- or frequency-domain instrumentation, but continuous wave NIRS users have to rely on the literature values for this parameter. On the other hand, the unknown partial volume fraction of the activated tissue causes greater uncertainties in the response magnitude than the DPF, and some researchers choose to report their results in units of $\mu$mm instead of $\mu$M. The systemic responses can be estimated if detectors with short source-detector separations are available and regressed out using, eg, superficial signal regression (SSR). Alternatively, if diffuse optical tomography (DOT) instrumentation, permitting the recording of a large range of source-detector separations, is used, it is possible to reduce the effects of superficial physiology on brain responses by using 3-dimensional image reconstruction and analyzing the brain voxel data for activations. This approach can also extend the field of view (FOV) to most of the cerebral cortex in 0–2 month infants with potentially numerous applications. By using a suitable experimental design, which avoids the subject’s heart rate being elevated due to stress, stimulus-coupled systemic effects can be minimized. Furthermore, HbR concentration changes in infants may not follow the typical pattern and may depend on the subject’s age, the region studied, and sleep and/or sedation state, among other factors. Reporting all three parameters (HbO$_2$, HbT, and HbR) is useful to provide a reference of the response patterns in different situations to aid interpretability and enable later meta-analysis.

Conclusions

Bilateral temporal areas are implicated in most emotional processing studies in children, independent of the stimuli used. Currently, it remains unknown which neural activation patterns reflect maturation and at what age the emotional encoding reaches those typically seen in adults. Longitudinal studies are currently scarce and are clearly needed to answer these questions better. Most NIRS studies on emotional processing in children have been done in infants, while there are limited studies carried out in children 1 to 2 years of age. Variance in typical emotional processing may have far-reaching implications for the later development of emotional, social, and cognitive skills in children. In addition to longitudinal repeated measures, functional neuroimaging might prove an important tool to study the associations between the early pattern of neural responses and socio-emotional development later in life.
