Transients have proven to be a specially demanding operation mode for rotor cages in induction motors. The combination of thermal and mechanical stresses causes damage in weak points of the secondary circuit of these machines. A 3D multiphysics computation may shed some light into the conditions under faults such as broken bars develop whilst taking into account phenomena as interbar currents. With the aim of reducing the computational cost involved, this work carries out a 3D simulation of just the rotor during the first 2.5 cycles after a direct-on-line connection, being the tangential component of the magnetic vector potential mapped on its iron surface from the results obtained by 2D locked rotor FE simulation. The results provide an insight into the skin effect and mechanical loads in the cage, a magnetic coupling between the end ring and the shaft as well as the limitations of the weakly coupled magnetoelastic analysis.

Index Terms—Induction motors, rotors, electromagnetic transients, magnetomechanical effects, fault diagnosis.

I. INTRODUCTION

Transients in induction motors have proven especially damaging for the rotor cage [1]. Frequent startups or stall periods of large units cause heavy thermal and mechanical stresses that in addition to structural or manufacturing weak spots develop into breakages of this secondary circuit [2].

Fatigue tests [3] and analytical calculations [4] have been the traditional methods for studying the development of this fault, since the complexity of a Finite Element electromagnetic, thermal and mechanical computation was too big to be carried out. In [3] FEM was used to obtain the speed, and hence the inertial forces during the acceleration of an induction's motor rotor in a startup transient. Separately, the effects of such forces were imposed on a mesh simulating a rotor bar joint to the end ring. Since no thermal effects were considered, the simulation did not correspond to experimental data. Another approach is considered in [4] in which analytical expressions are used to model the skin effect in the rotor bar during stall conditions, as well as its thermal and mechanical (thermal expansion) consequences.

However, if the results are to have impact on design and fault evolution modelling (prognosis) more detailed computations are needed. 3D FE is mandatory if phenomena as interbar currents are taken into account. Thus, this work presents the 3D electromagnetic and mechanical computation of a cage rotor during the first instants after a direct-on-line connection. In order to reduce the computational needs, a value of the magnetic vector potential is imposed on the rotor iron surface, thus not being simulated the stator. Furthermore,

weak coupling between the electromagnetic and mechanical solvers is established whilst, due to the short period simulated, temperature rise is not significant according to preliminary studies based on analytical models [5] and therefore no thermal computation is carried out.

II. APPROACH FOLLOWED

The formulations used for the electromagnetic and the magnetic forces analysis are presented here.

A. Electromagnetic Analysis

Several formulations for 3-D electromagnetic modelling are summarized in [6]. In this paper, the AV-A formulation is used for the 3-D simulation with open source FEM software ELMER which is also applied in [7, 8]. The formulation can be derived by means of a magnetic vector potential $\mathbf{A}$ ($\mathbf{B} = \nabla \times \mathbf{A}$) and an electric scalar potential V .

$$\mathbf{E} = -\frac{\partial \mathbf{A}}{\partial t} - \nabla V \quad (1)$$

$$\nabla \times \frac{1}{\mu} \nabla \times \mathbf{A} + \sigma \frac{\partial \mathbf{A}}{\partial t} + \sigma \nabla V = \mathbf{0} \quad (2)$$

$$\nabla \cdot \left(\sigma \frac{\partial \mathbf{A}}{\partial t} + \sigma \nabla V \right) = 0 \quad (3)$$

Here the magnetic vector potential $\mathbf{A}$ has three components (A_x, A_y, A_z). Equation (2) is derived from the Ampere's law and Faraday law (1), whereas (3) is a representation of the divergence free nature of currents. However, the complete 3-D model of machine has proved to be very computationally expensive as attempted in [9].

In order to avoid performing a complete 3-D machine simulation but keeping the 3-D analysis for rotor calculations, 2-D coupled 3-D formulations have been attempted yielding a considerable computational decrease as illustrated in [10]. Furthermore, the use of 2-D coupled 3-D simulation for electromagnetic and structural dynamics analysis of electrical machine is performed in [11]. Clearly, 2-D coupled 3-D FEM analysis is becoming popular, especially in simulating complex 3-D phenomena. Specifically, using this coupling,

V. Climente-Alarcon and R. Sundaria contributed equally.

rotor eddy current losses in induction machine laminations are calculated in [12]. Following that, the method used in this work presents a weak coupling between 2-D and 3-D field simulation i.e. the corresponding 2-D simulation is not affected by computed 3-D solution.

The field distribution within the rotor can be obtained by setting the normal components of the flux and current densities on its boundaries [6]. This normal component of $\mathbf{B}$ can be defined by imposing the tangential component of $\mathbf{A}$ on those same boundaries, as explained in [12]. Thus, in this work, the coupling between the 2-D field solution and the 3-D mesh is carried out specifying on the iron's surface the tangential component of $\mathbf{A}$, which is interpolated from the 2-D vector potential solution. That is, the A_z component obtained by a locked rotor 2-D FE simulation for the same time steps is mapped on the surface of the rotor following the skew of the bars. Magnetic and electric insulation is imposed on the external boundaries of air surrounding the end rings' regions. The concepts are illustrated in Fig. 1.

FIG.1. Boundary conditions in the 3-D rotor case when the source of the field is 2-D field solution (A_{2-D})

B. Nodal Forces

For the mechanical computation, the nodal forces are according to the virtual work principle obtained following the procedure used in [13]. No magnetostriction is taken into account. The magnetic force is calculated differentiating the magnetic energy with respect to a virtual displacement $\mathbf{f}_s$ that depends on a real parameter s such as $\lim_{s \rightarrow 0} \mathbf{f}_s(\mathbf{x}) \rightarrow \mathbf{x}$:

$$\begin{aligned} \frac{\partial W_s}{\partial s} &= \int \mathbf{H}(\mathbf{B}) \cdot \frac{\partial}{\partial s} \mathbf{J}_s \cdot \mathbf{B} \\ &- \frac{\partial \det \mathbf{J}_s}{\partial s} \left(\mathbf{H}(\mathbf{B}) \cdot \mathbf{B} - \int_0^B \mathbf{H} \cdot d\mathbf{B} \right) dx \end{aligned} \quad (4)$$

where a change of variables and the Piola transformation for the magnetic flux density have been applied. $\mathbf{J}_s$ is the Jacobian of $\mathbf{f}_s$. For $\mathbf{f}_s = \mathbf{x} + s\mathbf{u}N(\mathbf{x})$, where $\mathbf{u}$ is the unit vector and $N(\mathbf{x})$ a nodal shape function, (4) yields:

$$\begin{aligned} \frac{\partial W_s}{\partial s} &= \int \mathbf{H}(\mathbf{B}) \cdot \mathbf{u} \nabla N \cdot \mathbf{B} \\ &- \mathbf{u} \nabla N \left(\mathbf{H}(\mathbf{B}) \cdot \mathbf{B} - \int_0^B \mathbf{H} \cdot d\mathbf{B} \right) dx \end{aligned} \quad (5)$$

These nodal forces are applied in the linear elastic module as body forces and the dynamical equation for elastic deformation of solids solved.

As boundary conditions, the displacement at both ends of the rotor are limited by setting spring boundary conditions on the shaft's cross-sections.

III. SIMULATION

For comparison purposes two simulations for the first 2.5 cycles of the connection transient in fixed 1e-4 s time steps have been carried out using the rotor featuring closed slots studied in [5], whose dimensions are presented in Table 1. In the first one, one of the bars was narrowed in its connection to the end ring by reproducing the material removed by two drills, creating a hot spot, as shown in Fig. 2. The second one involved a fully symmetrical rotor (the drills were filled, in this case with aluminum instead of air for the simulation). The full mesh comprised 121,738 nodes and the simulations of the transient during 50 ms took 17 days in a PC.

TABLE 1 Rotor's geometric data

External radius	34.75 mm
Iron length	100 mm
Total length	140 mm
Number of bars	20
Radius, top of the bars	34.5 mm
Radius, bottom of bars	22 mm
Skew angle	18 °
Area of a bar	49.25 mm ²
Remaining area (hot spot)	4%
Shaft radius	14.275 mm
Ring height and initial width	15 mm
Opening angle (cone)	10 °
Groove depth	6 mm

The characteristics of the materials (aluminum, silicon steel) utilized in the simulation are summarized in Table 2, where σ stands for electrical conductivity, E for the young modulus, ν for Poisson ratio, Al for the aluminum cage and Fe for all the steel bodies in the rotor, either iron or shaft.

TABLE 2 Material parameters

σ_{Al}	$22 \cdot 10^8$ S
E_{Al}	$70 \cdot 10^9$ Pa
ν_{Al}	0.35
$\sigma_{iron,x}$	$4 \cdot 10^6$ S
$\sigma_{iron,y}$	$4 \cdot 10^6$ S
$\sigma_{iron,z}$	0
σ_{shaft}	$4 \cdot 10^6$ S
E_{Fe}	$193.1 \cdot 10^9$ Pa
ν_{Fe}	0.29

FIG. 2. Partial view of the mesh showing the hot spot in the connection of a bar to the end ring. The rotor iron has been removed.

For time constrain reasons, in this study both solvers were weakly coupled; therefore there is no influence of the elastic field on the magnetic field. Fig. 3 shows the tangential component of the magnetic vector potential applied on the rotor iron at two time steps, 25 ms and 50 ms (final time step).

FIG. 3 Magnetic vector potential tangential component applied at the bottom, middle and top of the rotor iron nodes at 25 ms (lower) and 50 ms (upper). The values in the z component have been displaced ± 0.01 m for visualization purposes.

IV. RESULTS

A. Electromagnetic results

Fig. 4 shows a cutaway view of the rotor featuring the hot spot 45 ms after connection. The highest values of the flux magnetic density are observed next to the iron surfaces and especially on top of the bars, as it corresponds to a locked rotor condition. Furthermore, a magnetic coupling between the

end ring and interbar currents and the shaft, just 5.25 mm apart in this small motor, is also appreciated. The integration of the magnetic energy in the shaft's end opposite to the hot spot yields an inductance value of $3.5 \cdot 10^{-11}$ H, three orders of magnitude below the value utilized in the 2D FE simulation for the end ring inductance.

FIG. 4 Magnetic flux density and magnetic potential 45 ms after connection. The coupling between the end ring and the shaft is observed.

The current density in the cage and shaft, showing the skin effect, is presented in Fig. 5. The distribution is the expected one for the geometry of the conductors and the excitation frequency involved.

FIG. 5 Current density in the cage and shaft 45 ms after connection.

Finally, the current density in the radial direction at the middle of the hot spot is depicted in Fig. 6, showing a higher heating rate on the top and the bottom of the saddle compared to the average, at some time almost three times greater. The

current in axial direction for the bar facing the saddle suffers a reduction of up to 3% (Fig. 7). It can also be appreciated some distortion on both ends of the diagram due to the reduction of the end rings' section. Since no aluminum is present at the top of the bars' ends, a sizeable amount of current crosses through the iron in these areas for this relatively high frequency and low iron resistance.

FIG. 6 Element current density across the hot spot in the radial direction x .

FIG. 7 Integrated current in the axial direction z for the bar facing the hot spot, ratio between the hot spot and symmetrical state.

B. Mechanical effects

The results obtained from the weakly coupled linear elastic solver are presented in this section.

Electromagnetic induced stresses do not represent a sizeable mechanical load in the cage compared to thermal induced ones [5], as it is shown in Fig. 8, where the main body forces are observed in the iron yoke and shaft, especially in its supporting ends, with values up to 300 MPa. The end ring slightly increases its stress level for the hot spot case (Fig. 9), remaining the ones around the saddle area similar in both states. The overall maximum values are obtained in the iron-aluminum interface, caused mainly by high tensile forces in the axial direction.

FIG. 8 Von Mises stress in the rotor 45 ms after connection.

FIG. 9 Comparison of Von Mises stress in the symmetrical (left) and hot spot (right) cases 45 ms after connection.

Finally, Fig. 10 depicts the variation of the average axial stress (z direction) on the end surfaces of the shaft for both the symmetrical rotor (dashed line) and the one featuring the hot spot in one of its end rings (solid line). The curves between both states begin to slightly differ after 35 ms around some local extrema. An offset of $3.94 \cdot 10^5$ Pa for the hot spot's end and $1.14 \cdot 10^5$ Pa for the opposite is observed for both cases. Also a main component at the field frequency of 50 Hz is clearly detected, rapidly blurred by high frequency ones at around 500 and 1420 Hz.

V. CONCLUSIONS

During the first instants after a direct-on-line connection the skin effect can cause substantial differential heating on imperfections in the rotor cage of an induction motor; however, electromagnetic-induced mechanical loads remain low. Under these conditions and for a small machine, a magnetic coupling between the end ring and interbar currents and the shaft is observed. The comparison of these results, obtained by means of a weakly coupled magneto-elastic

model, with a healthy rotor simulation shows minor differences in the forces acting at both shaft ends

FIG. 10 Stress at both end sections of the rotor for the hot spot case (solid line) and symmetrical one (dashed line). The arrows point out some small differences around the local extrema.
