Effect of MACE Parameters on Electrical and Optical Properties of ALD Passivated Black Silicon

Kexun Chen[†], Toni P. Pasanen[†], Ville Vähäniissi, and Hele Savin

Abstract—Metal-assisted chemical etching (MACE) enables efficient texturing of diamond-wire sawn multicrystalline silicon (mc-Si) wafers. However, the excellent optics are often sacrificed by polishing the surface to achieve better surface passivation with chemical-vapor-deposited (CVD) silicon nitride (SiN_x). In this work, we show that a polishing step is not required when CVD SiN_x is replaced with atomic-layer-deposited (ALD) aluminum oxide (Al_2O_3). Indeed, while polishing increases reflectance, it has in general only very modest effect on surface recombination velocity of ALD-passivated b-Si. Furthermore, since ALD Al_2O_3 is compatible with various surface morphologies due to its excellent conformality, the MACE parameters can be more freely adjusted. First, the concentration of silver nitrate (AgNO_3) in $\text{AgNO}_3/\text{H}_2\text{O}$ solution that is used to deposit Ag nanoparticles is shown to affect the final b-Si morphology. Instead of needle-shaped b-Si produced by 5 mmol/L AgNO_3 concentration, two orders of magnitude lower AgNO_3 concentration produces porous structures, which are more challenging to passivate. Additionally, we demonstrate that a separate Ag nanoparticle removal step in nitric acid (HNO_3) is not a prerequisite for high carrier lifetime. Instead, Ag nanoparticles present during polishing in a $\text{HF}/\text{HNO}_3/\text{H}_2\text{O}$ solution affect the final b-Si morphology by accelerating the etching of Si. The results demonstrate that no trade-offs are necessary between optical and electrical properties of MACE b-Si when using ALD.

I. INTRODUCTION

METAL-ASSISTED chemical etching (MACE) has high potential to become the mainstream texturing method for multicrystalline silicon (mc-Si) substrates, since it is able to efficiently reduce reflectance of diamond-wire sawn wafers [1]. Indeed, MACE-textured surfaces are often called black silicon (b-Si) due to their dark appearance, and hence, MACE b-Si has raised interest also as a more efficient texture for monocrystalline wafers. Furthermore, the technique can easily be adopted to existing solar cell production lines without the need for large investment to new equipment due to its wet-

chemical nature [2], [3]. However, the MACE-texture currently remains non-optimized from the optics perspective, since the nanostructures are typically polished to enable better conformality, and hence, more efficient surface passivation using chemical vapour deposited (CVD) silicon nitride (SiN_x) [4]–[6], which is widely used by the current PV industry. Due to polishing, reflectance of MACE-textured wafers remains as high as 15–30 % without anti-reflection (AR) coatings, and a thick SiN_x film is required to reduce reflectance to ~8–10 % [5], [6]. Surface passivation of MACE-structures with lower, <5 % reflectance has been demonstrated with thermally-grown silicon dioxide (SiO_2) [7], [8]. Although thermal SiO_2 grows conformally on nanostructures, the passivation efficiency is limited due to negligible density of fixed charges in the thin film [9]. Moreover, high-temperature oxidation after the MACE process increases the risk of metal contamination.

The challenges related to either conformality or high process temperature can be overcome by the application of atomic layer deposition (ALD). Indeed, excellent surface passivation has been obtained on dry-etched high-aspect-ratio b-Si using ALD aluminium oxide (Al_2O_3) [9], [10], also with an industry-scalable spatial ALD system [11]. Hence, the polishing step can likely be omitted, or at least substantially shortened, by replacing SiN_x with ALD Al_2O_3 , which improves the optical performance of the final device. Although most of the reports on MACE b-Si have concentrated on SiN_x , the excellence of ALD Al_2O_3 has been demonstrated in a few recent studies [12]–[16]. Rahman *et al.* reported surface recombination velocity (SRV) of 26 cm/s in silicon nanowires with 6 % reflectance [12], whereas Chong *et al.* achieved even better surface passivation using slightly shallower nanostructures with a combination of ~19 cm/s SRV and ~7 % reflectance [13]. Additionally, Parashar *et al.* recently demonstrated SRV of only ~5 cm/s on 50 μm thick flexible b-Si substrates using a nitrogen-doped Al_2O_3 thin film [16]. However, most of the studies have optimized the MACE parameters and the resulting b-Si morphology only from the optics perspective [17], [18], and disregarded surface passivation. Moreover, since the effect of MACE parameters on

electrical properties has earlier been discussed from the SiN_x passivation perspective, the application of ALD Al_2O_3 enables the possibility to optimize the parameters further to achieve more efficient combination of reflectance and SRV. The first demonstration by Chong *et al.* showed that SRV is surprisingly independent of the surface area enlargement of the MACE nanostructure, which was determined by the polishing time [13], but the effect of other process parameters, such as concentration of the solutions, remains ambiguous.

Although silver generates less electrically active deep-level defects in silicon than gold or copper, its involvement in the MACE process increases the risk of contamination due to its high diffusivity [19], [20]. Therefore, the nanoparticles are typically removed in HNO_3 after the nanotexturing process to prevent contaminating the bulk during following high temperature process steps, such as contact firing [5]–[7], [18], [21]. Nevertheless, a simplified process would result in faster throughput and cost savings, and hence, the exclusion of a separate Ag removal step would be favored.

In this paper, we study experimentally if the polishing step can be omitted by replacing SiN_x with ALD Al_2O_3 . Additionally, we investigate the effect of silver nitrate (AgNO_3) concentration in $\text{AgNO}_3/\text{H}_2\text{O}$ solution, which is used to deposit Ag nanoparticles, on optical and electrical properties of ALD-passivated MACE b-Si. We also try to simplify the nanotexturing process by studying, whether an Ag removal step in HNO_3 is necessary to obtain good electrical performance required for high-efficiency solar cells. To address these research questions, we first investigate the morphology of the b-Si samples fabricated using various etching parameters. We continue by analysing the optics of the MACE-textures, and finally, evaluate the efficiency of ALD surface passivation and whether metal contamination is an issue in the same nanostructured samples.

II. EXPERIMENTAL

Samples used in this study were quarters of 4" shiny-etched boron-doped p-type high-quality float-zone (FZ) silicon wafers (1 Ωcm , 250 μm , (100) orientation). The experimental process flow is presented in Fig. 1. A three-step MACE-process was used to enhance control over surface morphology [2], [13], [21]. First, Ag nanoparticles were deposited electrolessly by immersing hydrofluoric acid (HF)-treated samples in a $\text{AgNO}_3/\text{H}_2\text{O}$ solution with either 0.05 mmol/L or 5 mmol/L concentration of AgNO_3 (labelled “low $[\text{AgNO}_3]$ ” or “high $[\text{AgNO}_3]$ ”, respectively) for 20 s. Two clearly distinct AgNO_3 concentration levels were selected to limit the number of different variable combinations. The b-Si nanotexture was formed on both sides of the samples by a 2 min dip in a $\text{HF}/\text{H}_2\text{O}_2/\text{H}_2\text{O}$ solution ($\text{HF}(50\%):\text{H}_2\text{O}_2(30\%):\text{H}_2\text{O} = 25:10:270; \text{v:v:v}$) at room temperature under normal cleanroom lighting. Subsequently, the Ag nanoparticles were removed from half of the samples by immersing them in 69 % HNO_3 for 10 min, while the nanoparticles were left on the other half of the samples for the rest of the process (labelled “with Ag removal” or “without Ag removal”, respectively). The nanostructure fabrication was finished by polishing in a $\text{HF}/\text{HNO}_3/\text{H}_2\text{O}$ solution ($\text{HF}(50\%):\text{HNO}_3(69\%):\text{H}_2\text{O} =$

Fig. 1. Experimental procedure. The steps that have varied parameters are highlighted in red. Labels used in the subsequent figures are reported on the top.

3:50:70; v:v:v) for 0 s (i.e., no polishing), 30 s, or 60 s and rinsing in de-ionized water. Finally, the samples were dried using a nitrogen gun.

After the MACE process, the samples were cleaned with the RCA cleaning sequence. To enhance the stability and effectiveness of the bath, a commonly-used complexing agent, 1,2-cyclohexanediaminetetraacetic acid (CDTA), was added to the RCA1 solution [22], [23]. The oxide grown during the cleaning was left on the sample surfaces. Subsequently, the surfaces were passivated with double-sided ALD Al_2O_3 deposited at 200 $^\circ\text{C}$ using a TMA/ H_2O -based process and Beneq TFS 500 tool, similar to reported in [24]. Surface passivation was activated by a 30-minute annealing at 400 $^\circ\text{C}$ in nitrogen.

The samples were characterized by minority charge carrier lifetime measured with quasi-steady state photoconductance (QSSPC) technique (Sinton WCT-120) to evaluate the performance of surface passivation and to observe, whether possible metal contamination deteriorates the electrical quality of the bulk. In addition, the optical properties were evaluated by integrating sphere-based surface reflectance measurements (Agilent Cary 5000). Average reflectance (R_{ave}) weighted by the AM1.5G solar spectrum was calculated in the wavelength range of 300–1000 nm using equation

$$R_{\text{ave}} = \sum_{\lambda_i=300 \text{ nm}}^{1000 \text{ nm}} \left[\frac{I(\lambda_i)}{I_{\text{tot}}} \cdot R(\lambda_i) \right] \quad (1)$$

where λ_i is a single wavelength, $R(\lambda_i)$ and $I(\lambda_i)$ are the reflectance and spectral irradiance at the wavelength λ_i , respectively, and I_{tot} is the total irradiance in the inspected wavelength range, given by

$$I_{\text{tot}} = \sum_{\lambda_i=300 \text{ nm}}^{1000 \text{ nm}} I(\lambda_i). \quad (2)$$

Finally, the morphology of the MACE nanostructures was imaged by scanning electron microscopy (SEM, Zeiss Supra 40). Uncertainty of 5 % was assumed in both QSSPC and reflectance measurements.

III. RESULTS AND DISCUSSION

A. Surface morphology

The study investigates first the effect of MACE-parameters on b-Si morphology. Fig. 2 presents cross-sectional SEM images of the b-Si samples prior to (0 s) and after 30 s or 60 s of polishing. Within the samples without polishing, the AgNO_3 concentration in the $\text{AgNO}_3/\text{H}_2\text{O}$ solution has a prominent effect on the b-Si morphology. High $[\text{AgNO}_3]$ produces needle-shaped b-Si, whereas low $[\text{AgNO}_3]$ results in smaller and more porous nanostructures, which are likely more challenging to passivate. Similar observations have been reported also in earlier studies, which attributed the increasing porosity to reduced size and increased surface coverage of Ag nanoparticles with decreasing AgNO_3 concentration [17], [18].

Polishing in $\text{HF}/\text{HNO}_3/\text{H}_2\text{O}$ solution smoothens the nanostructures in all samples, which is natural, since the step is typically applied to modify the MACE texture to better suit for CVD SiN_x . Opposite to H_2O_2 that was used in the b-Si formation step, HNO_3 efficiently oxidizes silicon also without metal catalyst, and the grown oxide is simultaneously removed by HF [25], [26]. Consequently, silicon is etched from all

surfaces that are in contact with the chemicals and the average height of the b-Si nanostructures in the high $[\text{AgNO}_3]$ samples reduces from ~ 320 nm to ~ 250 nm and ~ 125 nm during 30 s and 60 s polishing, respectively. Correspondingly, polishing removes the porous layer from the low $[\text{AgNO}_3]$ samples and the surface structures gradually turn more similar to those on the high $[\text{AgNO}_3]$ samples. Indeed, after 60 s polishing, all samples start to resemble each other rather closely independent of the used AgNO_3 concentration. Moreover, another similar set of samples was polished for 180 s, and all surfaces became virtually flat independent of the AgNO_3 concentration or the presence of the Ag removal step. Hence, the 180 s samples were excluded from further inspection.

In the presence of Ag nanoparticles (i.e., “without Ag removal”), polishing produces slightly shallower and wider nanostructures than in the case, where the nanoparticles have been removed prior to the polishing step. This observation indicates that silver catalyzes the etching also in this solution, but the chemical mechanism is different from the b-Si formation step. When the HF concentration is sufficiently high compared to that of the oxidizing agent, such as H_2O_2 or HNO_3 , all electron holes generated at the nanoparticles are consumed at the Ag-Si interface and etching occurs only at the vicinity of Ag [3], [7], [27]. This is the case in the used $\text{HF}/\text{H}_2\text{O}_2/\text{H}_2\text{O}$ solution, and nanostructures or nanopores form. Instead, when the relative HF concentration is low, as in the $\text{HF}/\text{HNO}_3/\text{H}_2\text{O}$ solution, consumption of the generated holes is reduced at the

Fig. 2. SEM images of the ALD Al_2O_3 -coated b-Si samples prior to and after 30 s or 60 s polishing. Higher AgNO_3 concentration in the first step results in needle-shaped nanostructures, whereas lower AgNO_3 concentration produces nanoporous surface. Polishing reduces the size of the nanostructures in all samples. The same scale bar applies to all images.

nanoparticle-Si interface. Consequently, the excess holes diffuse to all silicon surfaces, which results in homogeneous oxidation and subsequent etching of the wafer [3], [7], [27]. Hence, the presence of Ag nanoparticles slightly increases the etch rate of silicon in the HF/HNO₃/H₂O solution, which results in accelerated polishing of the nanostructures. The effect is more distinct within the SEM images of the low [AgNO₃] samples, which may be due to the larger dimensions of the needle-shaped b-Si on the high [AgNO₃] samples that hinder small changes from being as noticeable.

B. Reflectance

Since the MACE-parameters were observed to greatly affect the surface morphology, the analysis proceeds next to the optical properties of such b-Si nanostructures. Fig. 3a shows reflectance spectra of the b-Si samples that have not been polished. All samples show less than 10 % reflectance in the whole inspected wavelength range between 300 nm and 1000 nm. Especially, reflectance of the high [AgNO₃] samples is only ~4 % at the maximum. The needle-shaped b-Si on those samples acts as an effective refractive index gradient and efficiently reduces light reflection in a wide range of wavelengths, as reported also earlier for similar nanostructures [28], [29]. In the low [AgNO₃] samples, the graded index effect is equally effective at short wavelengths. However, since the nanoporous layer is thinner than the nanostructures on the high [AgNO₃] samples, the effect is weaker in the long wavelength range, which is seen as an increase in reflectance [30].

Fig. 3b presents solar spectrum-weighted (AM1.5G) average reflectance of all the samples as a function of polishing time. Polishing increases reflectance of all samples, as expected based on the reducing nanostructure size (Fig. 2). The increase in reflectance is initially pronounced in the low [AgNO₃] samples, which is likely due to faster etching of the nanoporous structure compared to the larger needle-shaped structures on the high [AgNO₃] samples that have less surface area in contact with the chemicals. As the polishing proceeds, the difference between the high and low [AgNO₃] samples diminishes as the nanopores are eventually entirely removed and the surfaces become more similar, as was observed from the SEM images (Fig. 2).

On the other hand, the samples that were polished directly after b-Si formation (labelled as “without Ag removal”) show overall slightly higher reflectance than the equivalents, from which the Ag nanoparticles were removed. The increased reflectance is attributed to the accelerated polishing of the samples with Ag nanoparticles, which was observed also by SEM imaging. Although the catalytic effect of nanoparticles on the polishing process was not as evident in the SEM images of the high [AgNO₃] samples, the difference in reflectance between those samples with and without Ag removal indicates that the phenomenon occurs also with higher AgNO₃ concentration.

C. Minority charge carrier lifetime

From the optics perspective, as seen above, polishing of MACE-fabricated b-Si should be avoided as it increases

Fig. 3. (a) Reflectance spectra of the b-Si samples prior to polishing. The samples have an ALD Al₂O₃-coating on the nanostructure. The spikes at 800 nm wavelength are due to change of a grating. (b) Solar spectrum-weighted average reflectance of the b-Si samples as a function of polishing time in HF/HNO₃/H₂O solution. The average has been weighted by the AM1.5G spectrum in the wavelength range of 300-1000 nm. Note the different scales on the y-axes.

reflectance. However, excellent optics do not necessarily guarantee high-performance solar cells if the electrical properties are simultaneously impaired. Therefore, recombination at the nanotextured surfaces after ALD Al₂O₃ passivation is further investigated. Fig. 4a shows the effective minority charge carrier recombination lifetime of the same samples that have b-Si on both sides at an injection level of 10¹⁵ cm⁻³, which is a typical condition under one sun illumination. The figure reveals that all samples have an effective carrier lifetime on the order of hundreds of μ s even without polishing, which is sufficiently high for >20 %-efficient PERC solar cells [31]–[33].

The AgNO₃ concentration affects the behaviour of carrier lifetime as a function of polishing. In the high [AgNO₃] samples, polishing has only negligible effect on lifetime, which agrees with the observations of Chong *et al.* [13]. This indicates

Fig. 4. (a) Effective minority charge carrier lifetime of the ALD Al₂O₃-passivated b-Si samples as a function of polishing time. The lifetime values are reported at an injection level of 10¹⁵ cm⁻³. (b) Injection-dependent carrier lifetime of the non-polished high [AgNO₃] sample without Ag removal. Note the logarithmic axes in (b).

that the ALD thin film is capable of passivating needle-shaped b-Si efficiently independent of its dimensions and the reduction in nanostructure size by polishing provides no benefit for surface passivation. Hence, a polishing step is not a prerequisite for good electrical properties in MACE b-Si when using ALD, and surface recombination velocity of 30 cm/s is achieved in combination with 3.9 % reflectance without polishing (high [AgNO₃], without Ag removal), which is at the same level with earlier reports [12], [13].

Instead, the low [AgNO₃] samples show a trend of increasing lifetime as the polishing proceeds. This behaviour can be explained by the more porous surface of those samples (Fig. 2). Although the b-Si spikes on the high [AgNO₃] samples can be coated conformally with ALD Al₂O₃ independent of their size, resulting in efficient surface passivation, the nanopores are more challenging to passivate due to their extremely large surface area and complex structure. Hence, removal of the porous layer and reduction of the surface area by polishing enables more conformal deposition of the thin film and results in more efficient surface passivation. However, the reduced surface recombination does not guarantee enhanced performance of the final device, since it is obtained at the expense of optical properties (Fig. 3b).

Surprisingly, the b-Si samples, from which the Ag nanoparticles were not removed in HNO₃, show constantly higher lifetime than the samples with Ag removal, despite the potential risk of silver contamination. As discussed earlier, the

surface is smoothened more efficiently when the nanoparticles are present during polishing. Hence, it is possible that also the high [AgNO₃] samples have a very thin nanoporous layer at the surface, which is removed by polishing, resulting in reduced SRV. Nevertheless, the lifetime improvement by the exclusion of the Ag removal step is more significant within the low [AgNO₃] samples, where the removal of the nanoporous layer is more critical to efficient surface passivation.

High carrier lifetime in the samples that did not experience the Ag removal step indicates that the bulk remained uncontaminated. This conclusion is supported by the shape of the injection-dependent lifetime, namely the constant carrier lifetime at low injection, measured from the samples, from which the nanoparticles were not removed in HNO₃ (data for the non-polished high [AgNO₃] sample is shown as an example in Fig. 4b). Hence, the RCA cleaning that was performed prior to ALD may have removed the remaining nanoparticles. In addition to cleaning, the RCA solutions may have slightly altered the final morphology of b-Si, and hence, affected the optical and electrical properties of the nanostructures [29]. Nevertheless, the presented SEM images and all data correspond the properties at the same stage, i.e., after cleaning and thin film deposition. Alternatively, the temperature of annealing that was performed after Al₂O₃ deposition (400 °C) was insufficiently high to activate silver-related defects and impair carrier lifetime in the bulk [20]. Typical solar cell processes may include steps that have higher thermal load, such as contact firing, which needs to be considered. Moreover, although RCA cleaning could also assist the prevention of other detrimental contaminants in solar cell production, it is not the current standard for PV industry. Hence, the effectiveness of the applied cleaning solutions needs to be carefully analysed and balanced with their cost.

IV. CONCLUSION

This work demonstrated that a polishing step, which is typically applied after b-Si fabrication by MACE, is not a prerequisite for efficient surface passivation when the PECVD SiN_x is replaced with ALD Al₂O₃. While polishing increased reflectance by reducing the nanostructure size, it had in general only a very modest effect on SRV. However, the AgNO₃ concentration in the AgNO₃/H₂O solution, which was used to deposit Ag nanoparticles, had an effect on the porosity of the b-Si. Low AgNO₃ concentration produced a porous surface that required smoothening to improve the electrical performance, which simultaneously impaired the optical properties. Hence, the AgNO₃ concentration should be kept sufficiently high (in the mmol/L range) to achieve low reflectance and to prevent formation of nanoporous Si, which is challenging to passivate. Surprisingly, the highest lifetimes were achieved in samples, from which the Ag nanoparticles were not removed with HNO₃, although the risk of metal contamination was higher. The reduced SRV was likely due to accelerated polishing of the nanostructure induced by the Ag nanoparticles, which was observed also as increased reflectance. The nanoparticles were likely removed in RCA cleaning after the nanotexturing process, which prevented the contaminants from impairing bulk

lifetime. The results demonstrate that no trade-offs are required between optical and electrical properties of MACE b-Si by the application of ALD, when the MACE parameters are appropriately selected.

Kexun Chen received the D.Sc. (Tech.) degree in physical science and technology in 2018 from Soochow University, China. His research interests include surface texturization, especially nanostructured silicon, and surface passivation in silicon photovoltaics.

He is currently working as a postdoctoral researcher in the Department of Electronics and Nanoengineering, Aalto University, Finland.

Toni P. Pasanen received the B.Sc. degree in electrical engineering and M.Sc. degree in micro and nanosciences from Aalto University, Finland, in 2015 and 2017, respectively. He is currently pursuing towards the Ph.D. degree in micro and nanosciences in the same university.

His research is currently focused on implementation of nanostructured silicon in commercial silicon solar cells, surface passivation via atomic-layer-deposited thin films and defect engineering in silicon.

Ville Vähänissi received the D.Sc. (Tech.) degree in semiconductor technology in 2016 from Aalto University, Helsinki, Finland. His research interests include defect engineering in silicon, especially photovoltaics, as well as atomic layer deposition and its various applications in semiconductor devices.

He is currently working as a Staff Scientist at the Department of Electronics and Nanoengineering at Aalto University School of Electrical Engineering.

Hele Savin received the D.Sc. (Tech.) degree in semiconductor technology in 2005 from Aalto University, Finland.

Her research interests focus on material research in semiconductors, more specifically defect engineering in silicon, nanostructured silicon, light-induced degradation and silicon photodetectors.

She is currently an Associate Professor in the Department of Electronics and Nanoengineering, Aalto University, Finland.
