ABSTRACT

The object 4C 71.07 is a high-redshift blazar whose spectral energy distribution shows a prominent big blue bump and a strong Compton dominance. We present the results of a 2-yr multiwavelength campaign led by the Whole Earth Blazar Telescope (WEBT) to study both the quasar core and the beamed jet of this source. The WEBT data are complemented by ultraviolet and X-ray data from Swift, and by γ-ray data by Fermi. The big blue bump is modelled by using optical and near-infrared mean spectra obtained during the campaign, together with optical and ultraviolet quasar templates. We give prescriptions to correct the source photometry in the various bands for the thermal contribution, in order to derive the non-thermal jet flux. The role of the intergalactic medium absorption is analysed in both the ultraviolet and X-ray bands. We provide opacity values to deabsorb ultraviolet data, and derive a best-guess value for the hydrogen column density of $N_{H}^{\text{best}} = 6.3 \times 10^{20} \text{cm}^{-2}$ through the analysis of X-ray spectra. We estimate the disc and jet bolometric luminosities, accretion rate, and black hole mass. Light curves do not show persistent correlations among flux changes at different frequencies. We study the polarimetric behaviour and find no correlation between polarization degree and flux, even when correcting for the dilution effect of the big blue bump. Similarly, wide rotations of the electric vector polarization angle do not seem to be connected with the source activity.

Key words: galaxies: active – galaxies: jets – quasars: individual: 4C 71.07.

1 INTRODUCTION

Blazars are radio-loud active galactic nuclei (AGNs) with the peculiarity that one of the relativistic plasma jets points towards...
us. The jet emission undergoes Doppler beaming, with consequent flux enhancement, contraction of the variability time-scales and blueshift of the radiation. The blazar spectral energy distribution (SED), in the usual $\log (\nu F_\nu)$ versus $\log \nu$ plot, presents two bumps. The low-energy bump is produced by synchrotron radiation, while the origin of the high-energy bump is debated. According to leptonic models, high-energy photons are obtained through inverse-Compton scattering of soft photons on relativistic electrons, while in the hadronic scenario they are produced by acceleration of protons and/or particle cascades.

The blazar class includes BL Lac objects (BL Lacs) and flat-spectrum radio quasars (FSRQs), which were originally distinguished according to the equivalent width of their emission lines (Stickel et al. 1991). Following the unified scheme of AGN, the parent population of blazars are radio galaxies, with FRI and FRII grossly representing the unbeamed counterpart of BL Lacs and FSRQs, respectively (Urry & Padovani 1995). Understanding the affinity between blazars and other AGN classes can benefit from the study of the properties of the unbeamed blazar emission coming from the accretion disc and broad-line region (BLR). This is an extremely difficult task for BL Lacs, which usually have featureless spectra and no signature of disc radiation. In contrast, the spectra of FSRQs generally show broad emission lines. Moreover, their SED displays a big blue bump, and sometimes also a little blue bump, which are interpreted as contributions from the accretion disc and BLR and can reveal important information on the AGN nuclear zone, i.e. their quasar core.

One of the most promising candidates to study the unbeamed properties of blazars is the FSRQ 0836+710 (4C 71.07), whose SED shows a particularly luminous disc (Raiteri et al. 2014). Its redshift was estimated to be $z = 2.172$ by Stickel & Kuehr (1993) from the broad emission lines C iv $\lambda1549$ and C iii] $\lambda1909$, and $z = 2.18032$ by Lawrence et al. (1996), while McIntosh et al. (1999) derived a systemic redshift of $z = 2.218$ from the [O iii] $\lambda5007$ narrow line in H-band spectra. A detailed investigation of the spectroscopic properties of 4C 71.07 is presented in Raiteri et al. (in preparation). They estimated a systemic redshift of $z = 2.213$ from the Balmer H and Hβ broad emission lines. In the following, we will adopt this redshift value.

Asada et al. (2010) inferred a Faraday rotation measure gradient from multifrequency VLBI polarimetry, suggesting a helical magnetic field for the jet of 4C 71.07. Evidences in favour of a helical jet structure were presented also by Perucho et al. (2012b) based on very long baseline interferometry data. From the absence of a hotspot in the arcsec jet radio structure, Perucho et al. (2012a) concluded that the jet likely loses collimation and gets disrupted by the growth of helical instabilities.

Akyuz et al. (2013) analysed the multifrequency behaviour of the source during both a quiescent state in 2008–2011 and an active state in 2011. They found that the $\gamma$-ray emission correlates with the optical, but not with the radio emission and that the $\gamma$-ray spectrum becomes curved in active states.

From the theoretical side, in their analysis of high-redshift blazars, Ghisellini et al. (2010) applied a simple leptonic one-zone synchrotron and inverse-Compton model to the sources SED to derive information on the nuclear and jet physical parameters. For 4C 71.07, they estimated a black hole mass of $3 \times 10^9 M_\odot$, a size of the BLR of $1.5 \times 10^{18}$ cm, an accretion disc luminosity of $2.25 \times 10^{47}$ erg s$^{-1}$, a bulk Lorentz factor of 14 at the jet dissipation radius of $5.40 \times 10^{17}$ cm for a jet viewing angle of $3^\circ$.

With the aim of disentangling the beam from the unbeamed properties of this distant FSRQ to study both the jet and nuclear emission, we organized an intense multiwavelength monitoring effort in the period going from 2014 September to 2016 October. Optical (photometric and polarimetric), near-infrared, and radio monitoring was obtained by the GLAST-Agile Support Program (GASP) of the Whole Earth Blazar Telescope Collaboration1 (e.g. Villata et al. 2008; Raiteri et al. 2017b, and references therein). These observations were complemented by pointings of the Swift satellite approximately once a month, by optical spectroscopic monitoring at the 4.2-m William Herschel Telescope (WHT) and 2.5-m Nordic Optical Telescope (NOT), and by near-infrared spectroscopic observations at the 3.58-m Telescopio Nazionale Galileo (TNG), all in the Canary Islands. The continuous survey of the sky at $\gamma$-rays by the Fermi satellite completed the observing coverage at high energies. The $\gamma$-ray flaring activity in 2015 October–November detected by the Astrarivelatore Gamma ad Immagini LEGgero (AGILE) and by Fermi has been analysed in Vercellone et al. (2019). A detailed investigation of the broad emission-line properties is presented by Raiteri et al. (in preparation). In this paper, we analyse the photometric and polarimetric data acquired during the WEBT campaign together with the UV and X-ray data from Swift and $\gamma$-ray data from Fermi.

The paper is organized as follows: we first present and analyse in detail the radio-to-ultraviolet data acquired from both ground-based and space observations (Sections from 2 to 5). These data are used in Section 6 to reconstruct the low-energy bump of the source SED, to disentangle the synchrotron from the nuclear thermal emission, and to build an empirical model for the latter. We subsequently analyse the high-energy X-ray (Section 7) and $\gamma$-ray (Section 8) data and discuss the broad-band multiwavelength behaviour (Section 9). We finally present optical polarimetric observations (Section 10) and draw conclusions in Section 11.

## 2 Ground-Based Optical, Near-Infrared, and Radio Data

Optical observations for the WEBT campaign were performed at the following observatories: Abastumani (Georgia), Belogradchik (Bulgaria), Calar Alto2 (Spain), Crimean (Russia), Lowell (USA; Perkins telescope), Lulin (Taiwan), McDonald3 (USA), Mt. Maidanak (Uzbekistan), Pulkovo (Russia), Roque de los Muchachos (Spain; Liverpool, NOT, TNG, and WHST telescopes), ROVOR (USA), Rozhen (Belarus), SAI Crimean (Russia), Sirio (Italy), Skinakas (Greece), St Petersburg (Russia), Teide (Spain; IAC80 and STELLA-I telescopes), Tijarafe (Spain), Valle d’Aosta (Italy), Videojevica Astronomical Station (Serbia; 60 and 140 cm telescopes).

All data sets were processes with standard procedures. The source magnitude was obtained by differential aperture photometry, using reference stars in the same field of the source (Villata et al. 1997; Doroshenko et al. 2014; Larionov private communication). Further optical photometry was obtained as calibration information in support of the spectroscopic monitoring at the NOT and WHST telescopes (see Raiteri et al., in preparation).

3. In the framework of the telescope network of the Las Cumbres Observatory.
Overposition of data from different telescopes sometimes revealed offsets that were corrected for by shifting the most deviating data sets. Strong outliers showing up in only one band were removed. In some cases, data scatter was reduced through binning.

Near-infrared data in $J$, $H$, and $K$ bands were acquired at the Campo Imperatore Observatory (Italy). Additional data were obtained as calibration photometry for the near-infrared TNG spectra (see Raiteri et al., in preparation).

The final, cleaned, optical, and near-infrared light curves are shown in Figs 1 and 2, respectively. Notwithstanding the large sampling difference, especially between optical and near-infrared data, and different precision, the general increase of the variability amplitude from blue to red is evident and reveals the imprint of the emission contribution from the big blue bump, which is stronger in the blue (see Section 6).

Table 1 reports, for each band, the number of data in the final light curves, the variability amplitude $\Delta \text{mag} = \text{mag}_{\text{max}} - \text{mag}_{\text{min}}$ and the mean fractional variation (Peterson 2001)

$$f_{\text{var}} = \sqrt{\frac{\sigma^2 - \delta^2}{\langle F \rangle}}$$

where $\sigma^2$ is the data set variance, $\delta^2$ the mean square uncertainty of the fluxes (see Section 5 for the transformation from magnitudes to fluxes), and $\langle F \rangle$ is the mean flux of the data set. The advantage of $f_{\text{var}}$ is that it takes into account the data errors. A few flares are visible in the optical light curves in the period from JD = 2457320 to JD = 2457370 and then at JD = 2457443. The optical maxima were missed by the near-infrared observations, so we can expect that the near-infrared variability amplitude were actually higher than reported in Table 1.
Observations were checked for small-scale sensitivity (sss) problems, which occur when the source falls on small detector regions where the sensitivity is lower. The problem is more important for the ultraviolet filters. We found 35 snapshots in 8 epochs, where sss effects are recognized by the check procedure, all in the ultraviolet filters. These epochs are shown in Fig. 3. The data dispersion there is not larger than what happens in other epochs, so there is no need to exclude some of these frames from the analysis. Indeed, the most questionable points, lying out of the general trend common to all filters (e.g. the $v$-band point at JD = 2457128), are not due to sss problems.

As shown by Fig. 3 and Table 1, the source variability is smaller in the UVOT optical bands than in the ultraviolet, and this is a consequence of the fact that, due to the high redshift of the source, the big blue bump peaks in the $u$–$b$ bands (see Section 6).

The comparison with the ground-based data shown in Fig. 1 reveals that only the optical flaring period around JD = 2457330 is well covered by UVOT observations, which were triggered by the detection of a high γ-ray flux (Vercellone et al. 2019), while the other optical peaks were missed. As a consequence, the variation amplitude and mean fractional variability reported in Table 1 for the UVOT filters underestimate the actual variability of the source in the considered period.

### 4 Colour Behaviour

To investigate the source spectral behaviour, we first built ground-based $B - V$ colour indices by associating the most precise $B$ and $V$ data (error less than 0.03 mag) acquired within 15 min by the same telescope. We obtained 347 values, with an average index of 0.19 and standard deviation of 0.03.

Fig. 4 shows that the colour indices sample the whole brightness range of the source and clearly indicate a redder-when-brighter behaviour. Linear regression results in a slope of $-0.23$. This trend is expected if the source brightening is due to the increasing contribution of a ‘red’ variable synchrotron component to the (quasi) stationary emission of the big blue bump (e.g. Gu et al. 2006; Villata et al. 2006).

In the same figure, we show the $b - v$ colour indices obtained from UVOT data. We had to relax the constraints on the errors to get a reasonable number of colours. Using data with uncertainties less than 0.06 mag, we obtained 12 indices. They cover only the faintest states and indicate a mean value of 0.18, with standard deviation of 0.04, in agreement with the ground-based data.

### 5 From Magnitudes or Count Rates to Fluxes

Optical and near-IR magnitudes were transformed into flux densities by correcting for Galactic reddening according to the NASA/IPAC Extragalactic Database (NED) and using the absolute fluxes by Bessell, Castelli & Plez (1998).

By assuming a power-law shape of the optical spectrum $F_{\nu} \propto \nu^{-\alpha}$, we can derive the optical spectral index from the colours (see Fig. 4). The mean value obtained from the ground-based $B - V$ indices is $\alpha = 0.18$ with a standard deviation of 0.14.

As seen in the previous section, the average $B - V$ or $b - v$ colour is $\sim 0.2$ mag, which is outside the range of validity of the

6 http://ned.ipac.caltech.edu
the redshift of the source, the spectral region bluewards of the Ly\(\alpha\) to get deabsorbed flux densities. However, because of the high Galactic extinction according to the values in the same table to-flux conversion factors of Table 2 and then corrected for the count-to-flux conversion factor in the same band. The difference in \(<V>_b\) between the whole data set and the subset means that colour indices sample fairly well the range of brightness covered by the source. In the bottom panel, the linear regression line is plotted in red. The spectral index \(\alpha\) of the \(F_c \propto \nu^{-\alpha}\) law is shown on the right. Magenta squares and lines refer to UVOT data.

Breeveld et al. (2011) count rate to flux conversion factors for the UVOT ultraviolet bands. This means that the standard UVOT calibrations in the ultraviolet are not applicable to spectral types like that of our source. Therefore, to convert UVOT magnitudes into fluxes, we followed the recalibration procedure described in Raiteri et al. (2010) and applied to a number of cases thereafter (e.g. D’Ammando et al. 2012; Larionov et al. 2016). We convolve an average source spectrum with the UVOT filter effective areas to derive the effective wavelengths \(\lambda_{\text{eff}}\) and count-to-flux conversion factors \(CF\), and further with the mean extinction laws by Cardelli, Clayton & Mathis (1989) to obtain the extinction values \(A_j\). The procedure is then iterated to check stability of the results. Those reported in Table 2 were obtained with a log-linear fit to the source spectrum.

With respect to the Breeveld et al. (2011) calibrations, the most noticeable differences are a shift of about 100 Å in the effective wavelengths of the \(w1\) and \(w2\) bands and a \(\sim 5\) per cent increase of the count-to-flux conversion factor in the \(w1\) band.

Starting from the source count rates, we applied the count-to-flux conversion factors of Table 2 and then corrected for the Galactic extinction according to the values in the same table to get deabsorbed flux densities. However, because of the high redshift of the source, the spectral region bluewards of the Ly\(\alpha\) emission line is strongly eroded by a wealth of intervening absorbers.

Starting from the source count rates, we applied the count-to-flux conversion factors of Table 2 and then corrected for the Galactic extinction according to the values in the same table to-flux conversion factors of Table 2 and then corrected for the count-to-flux conversion factor in the same band. The difference in \(<V>_b\) between the whole data set and the subset means that colour indices sample fairly well the range of brightness covered by the source. In the bottom panel, the linear regression line is plotted in red. The spectral index \(\alpha\) of the \(F_c \propto \nu^{-\alpha}\) law is shown on the right. Magenta squares and lines refer to UVOT data.

(Scott, Bechtold & Dobrzycki 2000; Raiteri et al., in preparation). Therefore, to reconstruct the flux observed in the ultraviolet as it was emitted from the source, we must further correct for this effect. This issue will be addressed in the next section.

### 6 AN EMPIRICAL MODEL FOR THE QUASAR CORE

Based on infrared data from the Wide-field Infrared Survey Explorer (WISE) satellite, the Two Micron All-Sky Survey (2MASS), and the Campo Imperatore and Teide observatories, Raiteri et al. (2014) modelled the SED of 4C 71.07 from the infrared to the ultraviolet with the superposition of a log-parabolic jet component and a nuclear thermal component representing the emission contribution of the accretion disc and broad-line region. Because of the prominence of the big blue bump in this source, the nuclear thermal model was obtained by strengthening the type-1 QSO template by Polletta et al. (2007) with a blackbody. Thanks to the wealth of photometric and spectroscopic data we obtained in the WEBT 2-yr campaign, we can now refine the model for the source quasar core and estimate the thermal contribution of the nuclear emission to the source photometry in the various bands.

Fig. 5 shows the near-infrared to ultraviolet SED of 4C 71.07. All photometric and spectroscopic data have been corrected for the Galactic absorption. To build the core template, we started by considering the range of brightness spanned by the near-infrared, optical, and ultraviolet photometric data in the period considered in this paper. As mentioned before, the variability amplitude increases towards the red, and this is due to the increasing contribution of the very variable synchrotron emission with respect to the less variable thermal emission, which is assumed to be steady in the relatively short period of time we are dealing with.

In Raiteri et al. (in preparation), we present and discuss in detail the results of the spectroscopic monitoring of 4C 71.07 during the WEBT campaign. We obtained 24 optical spectra (12 with the WHT and 12 with the NOT) and 2 near-infrared spectra with the TNG. All of them were carefully calibrated in flux also using photometric supporting data. The average optical and near-infrared spectra are obtained by strengthening the type-1 QSO template by Polletta et al. (2007) with a blackbody. Thanks to the wealth of photometric and spectroscopic data we obtained in the WEBT 2-yr campaign, we can now refine the model for the source quasar core and estimate the thermal contribution of the nuclear emission to the source photometry in the various bands.
the log-parabolic shape of the thermal-subtracted SED that we will discuss in Section 9 suggests that we are not far from the real, elusive solution. By comparing the spectroscopic with the photometric information, we note that the source brightness level corresponding to the near-infrared spectrum is lower than that corresponding to the optical spectrum, therefore we use a power law with a lower normalization to describe the jet contribution to the near-infrared spectrum. By subtracting the jet flux from the spectral fluxes, we obtain the predicted nuclear component.

We lack source spectra in between the near-infrared and the optical spectrum as well as in the ultraviolet. Therefore, we complete the nuclear thermal model using available quasar templates. We adopted the TQSO1 template by Polletta et al. (2007), shifted to the systemic redshift of $z = 2.213$ (Raiteri et al., in preparation) and properly rescaled to smoothly join our optical and near-infrared spectra, to cover the wavelength range from 14900 to 9400 Å. The comparison between the prolongation of the TQSO1 template and the optical spectrum of 4C 71.07 corrected for the jet emission (see Fig. 5) reveals that the rising part of the big blue bump of this source is much harder that the average quasar spectrum, as found by Raiteri et al. (2014). This may be due to the fact that in other AGN the low-frequency part of the disc SED is usually contaminated by additional softer emission contributions, as suggested by Calderone et al. (2013).

For wavelengths shorter than 3740 Å, we use the ultraviolet quasar-stacked spectrum by Lusso et al. (2015). This was obtained by combining spectra of 53 quasars with redshift $z \sim 2.4$ acquired with the WFC3 instrument of the Hubble Space Telescope (HST). The authors present both the observed spectrum and that obtained by correcting for the absorption by the intergalactic medium (IGM). We use the former (Lusso private communication), properly scaled, to complete our ‘observed’ big blue bump template, while the IGM-corrected spectrum will be used to estimate effective opacity values in the photometric bands bluewards of the Lyα.

The final empirical model for the quasar core emission of 4C 71.07 is shown in Fig. 5. By convolving this template with the transmission curve of the Bessels and UVOT filters, we then calculate the photometric contributions of the big blue bump in the various bands. These are reported in Table 1 and can be used to subtract the thermal contributions to the source photometric observations when the purely non-thermal, jet emission is desired.

To further check the consistency of our procedure, we simulated a high brightness state. The broad-band jet emission is now modelled with a log-parabola, which is often used to describe the synchrotron contribution (e.g. Massaro et al. 2004; Raiteri et al. 2017b), as the power-law approximation would be too rough over such a

\begin{itemize}
  \item We had to apply a correction to the $u/2$ values to take into account that the template does not cover the whole range of frequencies spanned by the $u/2$ filter. The correction was done by shifting the $u/2$ thermal contribution to match the template.
\end{itemize}
of Ghisellini et al. (2010), there is a 6 per cent decrease in the
shown in Fig. 6.
Correct the UVOT data for IGM absorption. The opacity values are
effective opacity values due to such absorption were estimated by
Ghisellini et al. (2010) by averaging over all possible lines of sight.

Effective opacity values are satisfactorily reproduced, while the near-infrared maxima are
somewhat overproduced. This can be at least partly justified by the
fact that we lack near-infrared data at the epochs of the optical flux
peaks (see Section 2). In the ultraviolet, the range of the observed
data is satisfactorily reproduced too. These are encouraging results,
especially when considering that the ultraviolet template we used
(Lusso et al. 2015) is an average quasar spectrum and that the jet
emission spectrum can likely only approximately be described with
a log-parabolic model.

A further step is now necessary to correct for the IGM absorption.
Effective opacity values due to such absorption were estimated by
Ghisellini et al. (2010) by averaging over all possible lines of sight.
We rescaled those values (Ghisellini private communication) to
take into account the difference between the old standard effective
wavelengths by Poole et al. (2008) and ours. These new effective
opacity values $\tau_{\text{eff}}$ are listed in Table 2. With respect to the estimates of
Ghisellini et al. (2010), there is a 6 per cent decrease in the $w2$
band and a 2 per cent decrease in the $m2$ and $w1$ bands. The IGM-
corrected flux densities are obtained as $F_{\nu} = F \times \exp(\tau_{\text{eff}})$ and are shown in Fig. 6.

Another way of estimating the correction is to use the IGM-
corrected quasar spectrum of Lusso et al. (2015). By convolving
this spectrum with the UVOT filters effective areas, we obtain the
photometric contributions of the deabsorbed quasar core of 4C 71.07
(see Fig. 6). The differences between deabsorbed and absorbed SED
values allow us to estimate the average effective opacities and to
correct the UVOT data for IGM absorption. The opacity values are

\[ \tau_{\text{obs}} = \frac{F_{\text{obs}}}{F_{\text{corr}}} \]

8The ratio $T_{\text{c}} = F_{\lambda,\text{obs}} / F_{\lambda,\text{corr}}$ corresponds to the mean IGM transmission function of Lusso et al. (2015).

reported in Table 2, while corrected data are shown in Fig. 6. As can
be seen, following Lusso et al. (2015) leads to a higher correction than estimated by Ghisellini et al. (2010).

A final comment is due to remind that the disc emission of quasars
is variable and also in the case of 4C 71.07 a remarkable change (a
flux variation of a factor $\sim 2.5$) has been noted by Raiteri et al. (in
preparation). However, this occurred on a time span of more than 30
yr and indeed quasar flux changes are usually of the order of a
few tenths of mag on time-scales of several months/years (e.g. Kaspi
et al. 2000). This is much less than the variability characterizing the
non-thermal radiation from the jet.

7 DISC LUMINOSITY, ACCRETION RATE,
AND BLACK HOLE MASS

The empirical model built in the previous section allows us to
estimate the disc bolometric luminosity by integrating the thermal
continuum. This is obtained by fitting the big blue bump template with a cubic polynomial (see Fig. 7) and leads to the extremely high value $L_{\text{disc}} = 2.45 \times 10^{47}$ erg s$^{-1}$, assuming a luminosity distance of 17 585 Mpc. The main uncertainty comes from the high-energy part of the spectrum, which is poorly constrained. However, our estimate is in good agreement with the value $2.25 \times 10^{47}$ erg s$^{-1}$ calculated by Ghisellini et al. (2010) with a completely different procedure.

The peak of the thermal continuum is found at $\log v_{\text{rest}} \approx 15.46$
and implies a peak luminosity of $L_{\nu,\text{peak}} = 1.35 \times 10^{47}$ erg s$^{-1}$,
so that $L_{\text{disc}}(vL_{\nu})_{\text{peak}} = 1.8$, close to the factor of 2 usually assumed (e.g. Calderone et al. 2013; Ghisellini & Tavecchio 2015).
Moreover, the peak frequency is in agreement with that predicted by accretion disc models for the same luminosity (e.g. Hubeny et al. 2000).

We note that the rising part of our disc template fairly matches the
$F_{\nu} \propto \nu^{1/3}$ spectral distribution of a Shakura & Sunyaev disc
(Shakura & Sunyaev 1973) up to $\log v_{\text{rest}} \sim 15.25$
From the equation $L_{\text{disc}} = \eta M c^2$ (Shakura & Sunyaev 1973), we can derive the accretion rate $M$ once the efficiency of gravitational energy release $\eta$ is fixed. This can be as small as 0.06 for a Schwarzschild’s black hole and up to 0.32 for a rotating Kerr’s
black hole (Calderone et al. 2013). The disc bolometric luminosity we estimated above then leads to accretion rates of 17 and 3.3 $M_\odot$ yr$^{-1}$, respectively.

Calderone et al. (2013) proposed a method to estimate the black hole mass and accretion rate from the disc luminosity based on a Shakura & Sunyaev disc. By applying their equations (8) and considering that the isotropic disc luminosity is about one half the bolometric luminosity, we obtain $M_{BH} = (1.61 - 1.62) \times 10^9 M_\odot$ and $M = (18.0 - 18.3) M_\odot$ yr$^{-1}$ for viewing angles in the range $0 - 10^\circ$, as expected for a blazar. The Eddington luminosity is then $L_E = 1.6 \times 10^{47}$ erg s$^{-1}$ and the Eddington ratio is 0.66, a remarkably high value (e.g. Ghisellini & Tavecchio 2015). The black hole mass is somewhat smaller than that derived by Ghisellini et al. (2010), who found $3 \times 10^9 M_\odot$, but the difference is less than a factor of 2, which is the expected uncertainty on the results.

A comparison of the nuclear properties estimated above with those inferred from the analysis of the broad emission lines is deferred to Raiteri et al. (in preparation).

8 SWIFT-XRT

XRT data were processed with version 6.24 of the heasoft package and calibration files dated 20180710. We ran the xrt-pipeline on all observations in pointing mode in the period of interest and ended up with 21 observations in WT mode and 43 observations in PC mode. Because all WT observations have less than 1 min exposure, in the following we concentrate on the observations in PC mode. Many of them are piled-up, and the analysis of the source point spread function with the ximage tool indicates that the problem affects the inner 3 pixel radius core (1 pixel = 2.36 arcsec). To correct for pile-up, it is necessary to puncture the centre of the region from which the source counts are extracted and to reconstruct the PSF central maximum from the wings. To this aim, we first run the xrtcentroid tool to accurately identify the source coordinates on each image. Then, we extracted the source counts from an annulus with 3 and 30 pixel radii and the background counts in an annulus with 40 and 60 pixel radii centred on the source.

The source spectra, grouped in at least 20 counts per energy bin, were analysed in the 0.3–10 keV energy range with the Xspec package. We adopted the Wilms, Allen & McCray (2000) elemental abundances and a value for the Galactic absorption of $N_H = 2.76 \times 10^{20}$ cm$^{-2}$ (Kalberla et al. 2005).

The XRT data examined by Ghisellini et al. (2010) were modelled with a power law with Galactic absorption and the fit was very good from a statistical point of view ($\chi^2/\nu = 0.99$). Similarly, an analysis of the X-ray data acquired by XMM–Newton in 2001 by Vercellone et al. (2019) found only marginal evidence for absorption larger than the Galactic value; when left free, the hydrogen column density resulted in $N_H = (3.3 \pm 0.2) \times 10^{20}$ cm$^{-2}$. They fit the XRT data taken in 2015 with an absorbed power law with $N_H$ both free and fixed to the Galactic value. In the former case, values between 3.1 and $7.4 \times 10^{20}$ cm$^{-2}$ were obtained as well as higher spectral indices, i.e. softer spectra. Arcodia et al. (2018) studied the IGM absorption towards high-redshift blazars. They applied different models to the X-ray spectra of several sources, and concluded that the best results are obtained when assuming that the intrinsic spectrum is curved (e.g. a log-parabola) and there is some extra-absorption. They also noted that 4C 71.07 is an outlier in the $N_H(z)$ versus $z$ relation, showing smaller excess absorption than expected.

In the previous section, we saw that the UV emission of 4C 71.07 is likely to be strongly absorbed by the IGM. Therefore, we need to carefully investigate the role of absorption also at X-ray energies. We first compared the results obtained by fitting the XRT spectra with a power law with Galactic absorption to those obtained when $N_H$ is left free to vary. Fig. 8 shows that the improvement of the goodness of fit in the latter case is substantial, especially for some of the spectral fits. The best-fitting $N_H$ values are plotted in Fig. 9. They show a large range of values, with a mean $N_H = 6.4 \times 10^{20}$ cm$^{-2}$ and a standard deviation of $\sigma = 3.3 \times 10^{20}$ cm$^{-2}$. If we discard
The beamed jet and quasar core of 4C 71.07

Figure 10. Results of the Swift-XRT data analysis when adopting a power-law model with absorption fixed to $N_{\text{H}}^{\text{best}} = 6.3 \times 10^{20}$ cm$^{-2}$. Top: X-ray flux density at 1 keV versus time. Middle: Photon index $\Gamma$ versus time. Bottom: Photon index versus flux density.

We considered both a power-law and a log-parabola model for the source spectrum and a week time bin for the light curve. In Fig. 10, we show the $\gamma$-ray light curve in the 0.1–300 GeV energy range resulting from the power-law fit.

10 BROAD-BAND MULTIWAVELENGTH BEHAVIOUR

Fig. 11 compares the behaviour of 4C 71.07 at different wave-lengths, from the $\gamma$-rays to the radio band. The $\gamma$-ray light curve shows two prominent maxima at JD = 2457238 and JD = 2457336. We lack Swift observations at the time of the first maximum, but the X-ray flux was in a high state shortly before. The X-ray data exhibit a peak simultaneous to the second $\gamma$-ray maximum. Interestingly, another X-ray peak at JD = 2457325 corresponds to the maximum of the ultraviolet light curve, which in turn correlates with a major optical flare. The following three optical maxima are not covered by Swift observations. Their simultaneous $\gamma$-ray data show moderately high states. Other remarkable X-ray levels are reached at JD = 2457197, 2457511, and 2457607. The first event was preceded by a minor optical flare and a mild flux increase is also visible in the $\gamma$-rays. The second event has a possible, weak
peaks in the γ-ray and optical brightness states. Two SEDs correspond to the two γ-ray all frequencies but in the radio band, where a few days distance and then the radio flux declines. maximum is reached before the optical, X-ray and γ-8 GHz show little variability, while at 37, 86, and 228 GHz the flux notice higher fluxes in the period of increased optical activity. As to have any counterpart at all.

γ-ray spectra have been obtained with a power-law model with absorption fixed densities, so that these SEDs represent the synchrotron jet emission. The X-ray, but no optical, counterpart, and the third event does not seem to have any counterpart at all.

The near-infrared light curves are undersampled, so we can just notice higher fluxes in the period of increased optical activity. As for the radio bands, the 5 GHz data seem rather scattered, those at 8 GHz show little variability, while at 37, 86, and 228 GHz the flux maximum is reached before the optical, X-ray and γ-ray activity and then the radio flux declines.

Fig. 12 shows broad-band SEDs built with data simultaneous at all frequencies but in the radio band, where a few days distance was accepted because of the smoother flux variations at those wavelengths. We chose four epochs, corresponding to different γ-ray and optical brightness states. Two SEDs correspond to the two peaks in the γ-ray light curve, while the other two SEDs refer to the first and the fourth optical maxima. Swift data are available for only two SEDs. The plotted XRT data are available with a power-law model with absorption fixed to our best-guess value $N_H^{\text{best}} = 6.3 \times 10^{20} \text{ cm}^{-2}$. Fermi-LAT spectra are fitted with log-parabolic models but in the faintest state, where we show the results of a power-law fit, as the curvature parameter of the log-parabolic model was very small.

In the upper panel, the data in the $u$ and ultraviolet bands have been corrected for IGM absorption. Therefore, these SEDs represent the total deabsorbed emission of the source, including the quasar core and beamed jet contributions.

In the bottom panel, we subtracted the big blue bump contributions from the near-infrared, optical and ultraviolet fluxes according to the prescriptions given in Section 6. These SEDs thus represent the pure jet emission. In this representation, it is easier to see that increasing brightness states in the near-infrared to ultraviolet bands correspond to decreasing brightness states in γ-rays.

Log-parabolic fits to the data from the radio to the ultraviolet band highlight that the frequency of the synchrotron peak shifts towards higher values as the near-infrared-to-ultraviolet spectrum rises. A simple interpolation through the X-ray and γ-ray data allows us to verify that the same shift also applies to the inverse-Compton peak. Moreover, we can give a rough estimate of the Compton dominance, i.e. the ratio between $\nu F_\nu$ of the two peaks, in the two epochs where Fermi data are available. This ratio is about 70 at JD = 2457325 and about 200 at JD = 2457337.

The jet emission SEDs allow us to estimate the jet bolometric luminosity by integrating the synchrotron and inverse-Compton bumps. The result for the JD = 2457325 epoch, which represents a somewhat mean state, is $L_{\text{jet}} = 9.42 \times 10^{49} \text{ erg s}^{-1}$. 98.5 per cent of which is due to the high-energy bump. This extremely high luminosity is linked to the jet power spent in radiation by the relation (Ghisellini et al. 2014): $P_{\text{rad}} \approx 2 L_{\text{jet}} / \Gamma^2$, where $\Gamma$ is the bulk Lorentz factor. By considering a range of possible $\Gamma$ values, from $\Gamma = 14$ (Ghisellini et al. 2010) to $\Gamma = 28$ (Savolainen et al. 2010), we find $P_{\text{rad}} = (2.40–9.61) \times 10^{47} \text{ erg s}^{-1}$. This puts 4C 71.07 close (within 1–2 $\sigma$) to the best-fitting linear correlation between radiative jet power and disc luminosity derived by Ghisellini et al. (2014) and confirms the validity of this relation at the highest blazar energies.

11 POLARIMETRIC OBSERVATIONS

Synchrotron emission is polarized and in blazars the degree of polarization ($P$) and electric vector polarization angle (EVPA) can be extremely variable (e.g. Smith 1996). The polarization properties are expected to mirror the properties of the magnetic field in the emission region(s) and hence they can potentially shed light on the jet physics and structure. Actually, it is not clear yet to what extent stochastic processes due to turbulence act in determining the polarization behaviour in blazars (e.g. Marscher 2014; Kiehlmann et al. 2017; Raiteri et al. 2017a). Large EVPA rotations have been observed that are sometimes correlated with flares detected at γ-rays (e.g. Blinov et al. 2018). The picture appears quite complex, as changes in the jet viewing angle can mimic a stochastic process even when the variations in flux and $P$, and EVPA rotations, are produced by a deterministic process (Lyutikov & Kravchenko 2017).

Polarization data for this work were acquired at the Calar Alto, Crimean, Lowell, and St. Petersbursk observatories. The $P$ and EVPA behaviour in time is plotted in Fig. 13 and compared with the γ-ray and optical light curves. The optical light curve shows the contribution of the jet to the $R$-band flux densities, $F_{\text{jet}} = F_{\text{tot}} - F_{\text{BBB}}$, where...
The observed degree of polarization varies very fast, ranging from about zero (0.03 per cent) to 11 per cent. We have no data simultaneously with the $\gamma$-ray and optical peaks, except for the first major optical peak at JD $= 2457325.5$, where $P_{\text{obs}} = 6.5$ per cent. The somewhat sparse sampling and large errors affecting many polarization data points prevent us to draw firm conclusions, but there seems to be a lack of correlation between $P$ and the flux (see also Fig. 14) that remains true even when we correct $P_{\text{obs}}$ for the dilution effect of the big blue bump to derive the degree of polarization of the jet: $P_{\text{jet}} = (F_{\text{jet}} \times P_{\text{obs}}) / F_{\text{BBB}}$. The minimum and maximum values of $P_{\text{jet}}$ are 0.11 per cent and 47 per cent, respectively. The maximum is more than four times higher than the observed maximum value. We recall that the degree of polarization of the jet is $0.11$ per cent and $47$ per cent, $(2 - 3)$ (Rybicki & Lightman 1979). A value for $F_{\text{BBB}}$ higher than what we have assumed would further increase $P_{\text{jet}}$, pushing its maximum towards the above theoretical value. Therefore, polarization can potentially be used to constrain the emission contribution from the big blue bump in FSRQs.

$F_{\text{BBB}} = 0.532$ mJy is the big blue bump contribution, as obtained in Section 6 and listed in Table 1.

The observed degree of polarization varies very fast, ranging from about zero (0.03 per cent) to 11 per cent. We have no data simultaneously with the $\gamma$-ray and optical peaks, except for the first major optical peak at JD $= 2457325.5$, where $P_{\text{obs}} = 6.5$ per cent. The somewhat sparse sampling and large errors affecting many polarization data points prevent us to draw firm conclusions, but there seems to be a lack of correlation between $P$ and the flux (see also Fig. 14) that remains true even when we correct $P_{\text{obs}}$ for the dilution effect of the big blue bump to derive the degree of polarization of the jet: $P_{\text{jet}} = (F_{\text{jet}} \times P_{\text{obs}}) / F_{\text{BBB}}$. The minimum and maximum values of $P_{\text{jet}}$ are 0.11 per cent and 47 per cent, respectively. The maximum is more than four times higher than the observed maximum value. Therefore, polarization can potentially be used to constrain the emission contribution from the big blue bump in FSRQs.

The beamed jet and quasar core of 4C 71.07
by making use of the quasar templates by Polletta et al. (2007) and Lusso et al. (2015), respectively. From the model we derived the flux contributions of the big blue bump to the source photometry in the various near-infrared, optical, and ultraviolet bands. These can be subtracted from the observed fluxes to obtain the synchrotron jet fluxes. Following Ghisellini et al. (2010) and Lusso et al. (2015), we also estimate the opacity values that can be applied to the UVOT data to correct for the IGM absorption.

We analysed the XRT data with different models and estimated a best-guess value for the total absorption due to both the Galaxy and IGM of $N_{\text{HI}} = 6.3 \times 10^{20} \text{cm}^{-2}$, which is more than twice the Galactic value. The modest number of counts of the XRT spectra does not allow us to distinguish whether some intrinsic spectral curvature is present.

Light curves at different frequencies do not show persistent correlation, in particular among γ-rays, X-rays, and optical fluxes.

Broad-band SEDs present, beside a prominent big blue bump, a very strong Compton dominance. The correction for the IGM absorption makes the ultraviolet spectrum harder and the X-ray spectrum softer, and this implies a smoother connection between them.

We verified that 4C 71.07 is characterized by extreme nuclear and jet properties. Integration of the thermal continuum traced by our big blue bump template allowed us to estimate the disc bolometric luminosity, $L_{\text{disc}} = 2.45 \times 10^{47} \text{erg s}^{-1}$, and to derive the mass accretion rate, $M \simeq 18 M_\odot \text{yr}^{-1}$, and black hole mass, $M_{\text{BH}} \simeq 1.6 \times 10^8 M_\odot$, from it in the case of a Shakura & Sunyaev disc. As a consequence, the Eddington ratio is as high as 0.66. On the other hand, we could estimate the jet bolometric luminosity integrating the nuclear-subtracted SED, obtaining $L_{\text{jet}} = 9.42 \times 10^{49} \text{erg s}^{-1}$. From this, we calculated the jet radiation power, $P_{\text{rad}} = (2.40-9.61) \times 10^{47} \text{erg s}^{-1} \simeq (1-4) L_{\text{disc}}$. The disc and jet luminosities of 4C 71.07 are thus found to fit fairly well into the jet-disc relation for blazars (Ghisellini et al. 2014), confirming it at the highest energy values.

The polarization data acquired during the WEBT campaign display strong variability in both the polarization degree and polarization angle. This variability seems not to be correlated with the flux behaviour. Correction of $P$ for the dilution effect of the thermal radiation from the quasar core brings the maximum from $\sim 11$ per cent to $\sim 47$ per cent, but does not lead to a correlation with the flux. Noticeable EVPA rotations are observed, both clockwise and counterclockwise. They mostly occur during periods where the flux does not show significant changes and may be caused by turbulence.

In the light of our results, we conclude by stressing the importance of taking in due consideration the contribution of the quasar core when analysing the emission from FSRQs and the role of IGM absorption when dealing with high-redshift objects.

ACKNOWLEDGEMENTS

We thank an anonymous referee for stimulating comments and Elisabetta Lusso and Gabriele Ghisellini for sharing results of previous publications.
