Abstract

Some neurological patients with primary visual cortex (V1) lesions can guide their behavior based on stimuli presented to their blind visual field. One example of this phenomenon is the ability to discriminate colors in the absence of awareness. These so-called patients with blindsight must have a neural pathway that bypasses V1, explaining their ability to unconsciously process stimuli. The pathways that have been most often hypothesized to be the cause of blindsight connect lateral geniculate nucleus (LGN) or superior colliculus (SC) to extrastriate cortex, most likely V5, and parietal areas. To test if similar pathways function in neurologically healthy individuals or if unconscious processing depends on early visual cortex, we disturbed the visibility of a chromatic stimulus with metacontrast masking (Experiment 1) or neuronavigated transcranial magnetic stimulation (TMS) of early visual cortex, exact target being retinotopically mapped V1 (Experiment 2). We measured unconscious processing using the redundant target effect (RTE), which is the speeding up of reaction times in response to dual stimuli compared with one stimulus, when the task is to respond to any number of stimuli. An unconscious chromatic RTE was found when the visibility of the redundant chromatic stimulus was suppressed with a visual mask. When TMS was targeted to the correct retinotopic location of V1, and conscious perception of the redundant chromatic stimulus suppressed, the RTE was eliminated. Whether the elimination of unconscious RTE during TMS was exclusively due to disruption of V1 activity, or whether it was due to the possible interference with processing in V2 or even V3, is discussed. Based on our results and converging evidence from previous studies, we conclude that unconscious processing of chromatic information depends on the early visual cortex, in neurologically healthy participants.

Keywords: Redundant target effect, TMS, V1, early visual cortex, unconscious vision, blindsight, color perception

1. Introduction

Clinical cases of blindsight suggest a dissociation between conscious visual perception and unconscious visually guided behavior (Pöppel, Held, & Frost, 1973; Weiskrantz, Warrington, Sanders, & Marshall, 1974). Patients with blindsight have a visual field loss due to primary visual cortex (V1) lesions, but they can process visual information presented to that blind field. Manifestations of these residual capacities are assumed to be caused by different pathways bypassing V1 (Dankert & Rosetti, 2005), but all these have two aspects in common: V1 lesions and the ability to guide behavior based on visual information that the patients reportedly do not see. This phenomenon has led to the conclusion that unconscious visual processing does not rely on the same neural processes and brain areas as those used in conscious vision. The neural basis of blindsight is assumed to be pathways connecting subcortical structures to extrastriate and parietal areas. Most blindsight studies are not explicitly expressing the exact pathway enabling the residual abilities, but those that do, typically assume that LGN to V5 (Ajina & Bridge, 2018; Ajina & Bridge, 2019) or SC to V5 (Barbur, Watson, Frackowiak, & Zeki, 1993; Tamietto, et al., 2010) are important. In this study, we investigated whether neurologically healthy individuals could unconsciously guide their behavior based on chromatic information that they do not consciously perceive due to transcranial magnetic stimulation (TMS) of their V1. Studies on patients with blindsight have revealed that the patients can discriminate colors that they do not consciously perceive (Brent, Kennard, & Ruddock, 1994; Stoerig & Cowey, 1989, 1992) and that unconscious processing of chromatic information can prime faster reaction times (Tamietto et al., 2010). However, it is impossible to generalize the findings from patients with blindsight to the healthy population because new connections are formed and existing connections are

modified due to neural plasticity after the lesion (Payne & Lomber, 2001; Leh, Johansen-Berg, & Ptito, 2006). Blindsight may be the result of these neuronal changes rather than a property of an intact human brain.

Using TMS makes it possible to study the causal role of a brain area in a specific task performed by neurologically healthy individuals. TMS induces electrical activation which can temporarily disrupt normal processing in the stimulated cortical region. TMS of early visual cortex can suppress the conscious perception of a stimulus (Amassian, et al., 1989; for extensive review on the influence of TMS on conscious perception and forced-choice visual tasks, see de Graaf, Koivisto, Jacobs, & Sack, 2014), demonstrating the same effect that lesion studies (Holmes, 1918) have shown—the region performs a causal role in conscious perception. Since then, studies have tried to demonstrate that after suppressing conscious perception of a stimulus with TMS pulses to V1, it is possible to reveal “TMS-induced blindsight” in neurologically healthy observers. TMS of V1 necessarily stimulates also V2 and even V3 to a degree. Therefore, these studies are all based on underlying assumption that blindsight is not mediated by these lower extrastriate areas, but higher areas, such as V3a, V4, V5 or parietal areas. Some of the studies have found evidence of this phenomenon with varying stimulus types (Koenig & Ro, 2018; Boyer, Harrison, & Ro, 2005; Railo & Koivisto, 2012; Ro, Shelton, Lee, & Chang, 2004; Christensen, Kristiansen, Rowe, & Nielsen, 2008), suggesting that unconscious processing could in fact be possible without V1 (and V2/V3). However, majority of these studies have concluded that both conscious and unconscious visual processing rely on the early visual cortex in neurologically healthy individuals (de Graaf, Koivisto, Jacobs, & Sack, 2014; Hurme, Koivisto, Revonsuo, & Railo, 2017, 2019; Koivisto, Henriksson, Revonsuo, & Railo, 2012; Koivisto, Mäntylä, & Silvanto, 2010; Persuh &

Ro, 2013, Railo, Andersson, Kaasinen, Laine, Koivisto, 2014; Sack, van der Mark, Schuhmann, Swarzbach, & Goebel, 2009; Loyd, Abrahamyan, & Harris, 2013)

In this study, we employed a method called the redundant target effect (RTE) to measure the effects of unconscious stimuli on behavior. RTE involves speeding up reaction times when a participant is presented with two stimuli instead of one in a paradigm where the task is to respond as fast as possible when a single stimulus or two stimuli are presented. During the two-stimulus condition, the additional target is called the redundant target because it is not necessary for the task performance. RTE has been found even when the redundant target is reported as unconscious in patients with V1 lesions (Marzi, Tassinari, Aglioti, & Lutzemberger, 1986; Tamietto et al., 2010; Tomaiuolo, Ptito, Marzi, Paus, & Ptito, 1997) and in neurologically healthy participants (Hurme et al. 2017, 2019; Savazzi & Marzi, 2002). A promising candidate that can explain the unconscious RTE is a neural pathway that connects superior colliculus (SC) to extrastriate cortex and bypasses early visual cortex (Savazzi & Marzi, 2004). The role of this pathway in unconscious processing is very difficult to verify in humans. Sumner, Adamjee, and Mollon (2002) propose that S-cone isolating short-wavelength color stimuli can be used to test the contribution of the SC because studies on primates have suggested that SC is not activated by short-wavelength stimuli (Marocco & Li, 1977; Schiller & Malpeli, 1977; de Monasterio, 1978).

This short- versus long-wavelength paradigm has been used to study the role of the SC in the unconscious RTE. As measured with RTE, blindsight has been found using long-wavelength stimuli, but RTE is absent in response to short-wavelength purple stimuli (Tamietto et al., 2010). Importantly, Tamietto et al. (2010) did not observe functional magnetic resonance imaging (fMRI) activation in the SC with short-wavelength purple

stimuli, but with gray stimuli, SC activation was observed. The authors conclude that the unconscious RTE without early visual cortex is possible with long-wavelength stimuli but not with short-wavelength stimuli because the unconscious RTE is mediated by tracts connecting SC to occipito-temporal extrastriate areas. Leh, Mullen, and Ptito (2006) have previously demonstrated that patients with blindsight show RTE of achromatic stimuli but not of S-cone isolating short-wavelength stimuli, but Tamietto et al. (2010) were the first to show the dissociation between short- and long-wavelength colors in blindsight. The unconscious processing of luminance-masked long-wavelength stimuli found by Tamietto et al. (2010) seems to rule out the possibility that the colliculus can only mediate the unconscious processing of information related to achromatic stimuli. While the SC is not assumed to rely on color-opponent information transmitted to the cortex (White, Boehnke, Marino, Itti, & Munoz, 2009), it is possible that collicular neurons still show some sensitivity to a stimulus wavelength, similar to magnocellular neurons (Lee & Sun, 2009; Chatterjee & Callaway, 2002).

Although Tamietto et al. (2010) found an interesting dissociation between short and long wavelengths, their conclusion that RTE is mediated by the SC can be questioned. The possibility to eliminate SC activity using short-wavelength stimuli has been recently challenged by showing that express saccades (fast saccades triggered by SC neurons) can be elicited by S-cone isolating stimuli (Hall & Colby, 2016), and S-cone isolating stimuli can in fact activate the SC (Hall & Cloby, 2014). Another blindsight case shows an RTE produced by an unconscious achromatic redundant stimulus, but the RTE is absent for both unconscious S-cone isolating stimuli and L- and M-cone isolating stimuli (Marzi, Mancini, Metitieri, & Savazzi, 2009). These results indicate that blindsight in general is not a systematic finding

and that there are individual differences among neurological patients with V1 lesions (Marzi et al., 1986). Furthermore, there is evidence that neurological patients who show blindsight (as measured with RTE) have functional connections from their V1 lesion-sided SC to ipsi- and contralateral extrastriatal areas, whereas patients with no blindsight ability lack these connections (Leh et al., 2006).

The findings of Tamietto et al. (2010) have not been replicated in neurologically healthy participants (Railo et al., 2014). TMS of early visual cortex has been used to disturb the conscious perception of the color stimulus, and the unconscious RTE has been compared between blue and red colors. No RTE has been found with either color when the redundant stimulus is suppressed by TMS. However, Railo et al. (2014) did not demonstrate that the stimuli they used could produce an unconscious RTE even when the early visual cortex activity is not suppressed with TMS. Thus, their finding could merely show that the behavioral paradigm they used was not sufficiently sensitive to measure unconscious chromatic processing. Similar to the study on patients with blindsight (Tamietto et al., 2010), Railo et al. (2014) used rapidly flickering luminance masking to ensure that the participants could only rely on chromatic information in the RTE task. The flickering mask, which is a strong, attention-capturing stimulus, might have interfered with the participants' ability to unconsciously process the chromatic targets. In patients with blindsight, luminance masking may not pose a similar problem because they do not consciously perceive the luminance mask in their blind field. It is impossible to produce long-lasting, unconscious luminance masking with TMS because of the limited strength of TMS suppression. Consequently, the participants consciously perceive the luminance mask, but the color stimulus in the same visual field is suppressed from their consciousness by TMS. With this in mind, we modified

the paradigm in the present study to make the luminance mask unnecessary. In contrast to the traditional RTE paradigm, where either one or two stimuli are presented, in the present study, the participants were always presented with two stimuli that were perceived as equally bright, but they were instructed to respond only if they saw a chromatic stimulus. We previously used a similar type of paradigm to examine unconscious processing of motion with the RTE (Hurme et al., 2019).

In Experiment 1, we used a metacontrast mask to disturb the perception of the color of the redundant stimulus, and we tested if this unconscious chromatic information still influenced the reaction times. We expected to find unconscious processing using both S-cone isolating short-wavelength blue stimuli and M- and L-cone isolating long-wavelength red stimuli because unconscious processing of a metacontrast masked color has been previously demonstrated (Breitmeyer, Ogmen, & Chen, 2004; Breitmeyer, Ro, Ögmen, & Todd, 2007).

In Experiment 2, the behavioral task was identical to that in Experiment 1, but we disturbed the conscious perception of the redundant stimulus' color by TMS of V1. We formulated two hypotheses. First, if unconscious processing of chromatic information does not depend on early visual cortex, we expected to observe an RTE even when the participants do not report perceiving the redundant color target. Furthermore, if the mechanism suggested by Tamietto et al. (2010) is generalized to healthy participants, we expected to observe an unconscious RTE only in response to red (but not blue) stimuli. This dissociation could reflect the contribution of SC (Sumner et al., 2002; Tamietto et al., 2010) but could also be caused by magnocellular pathways that are largely insensitive to S-cone stimuli (Chatterjee & Callaway, 2002; Lee & Sun, 2009). Second, if unconscious processing of chromatic stimuli depends on the early visual cortex, we should find no unconscious chromatic RTE. This

hypothesis is consistent with the brain imaging evidence that clearly shows activation of V1 during color perception (Schluppeck & Engel, 2002). About half of the cells in V1 are selective to color; for example, early processing related to color constancy occurs already in V1 (Gegenfurtner & Kiper, 2003). Unconscious chromatic processing may rely on V1, similar to conscious processing.

2. Methods

2.1. Participants

Twenty participants (6 males, mean age = 23.3, SD = 3.6) took part in Experiment 1, where visual consciousness was manipulated using metacontrast masking. The participants were university students who participated in the experiment to obtain course credits in an introductory psychology course. Eighteen novel participants (2 males, mean age = 25.5, SD = 4.9) took part in Experiment 2, where visual consciousness was suppressed with TMS of V1. The participants in Experiment 2 were paid a small compensation. The study was conducted in accordance with the Declaration of Helsinki and with each participant's understanding and written consent. It was also approved by the ethics committee of the Hospital District of Southwest Finland.

2.2. Stimuli

The stimuli were presented on a 24" VIEWPixx/EEG LCD monitor with a refresh rate of 120 Hz and a resolution of 1920 × 1080 pixels. The monitor was centered on the participant's eye level, and the participant was seated 150 cm from it. The stimuli were presented 2°

from the central fixation cross in the bottom left and right quadrants. The stimuli were 0.17° dots, presented against a light gray background (68.8 cd/m^2) for one frame (8.3 ms). The stimulus colors were purplish blue (hereafter, blue), red, and gray. The blue stimulus (12.9 cd/m^2 , colorimetric values: $x = 0.16$, $y = 0.07$) was the same for all participants, but the intensities of the red (colorimetric values: $x = 0.64$, $y = 0.33$) and the gray (colorimetric values: $x = 0.30$, $y = 0.30$) stimuli were defined for individual participants so that the perceived luminance was the same between the colors. This was done using a heterochromatic flicker fusion (HFF) task (Lee, Martin, & Valberg, 1988). The participants were presented with a disk (2°) of alternating blue and red colors at a 60-Hz frame rate. They adjusted the intensity of the red RGB channel (all other channels had zero intensity) using a gamepad. When they could not detect the flickering, the red and the blue disks had the same perceived luminance. After adjusting the red color, they performed the same task for the gray stimulus. This time, one increment using the gamepad changed all the RGB channels one bit so that the stimulus always remained achromatic. The HFF was performed twice, first starting with full intensity (fully red or white) and then starting with zero intensity (fully black). The mean of the two obtained HFF values was selected to represent the red and the gray colors in the experiment. In Experiment 1, the measured luminance of the red stimulus was on average 13.3 cd/m^2 ($SD = 2.4$), and that of the gray stimulus was on average 14.5 cd/m^2 ($SD = 3.0$). In Experiment 2, the luminance of the red stimulus was on average 14.3 cd/m^2 ($SD = 1.3$), and that of the gray stimulus was on average 15.9 cd/m^2 ($SD = 2.2$).

2.3. Procedure

The experiments started with the HFF task (see Section 2.2. Stimuli), where the participants adjusted the colors of the red and the gray stimuli, as described above. A practice block of 40 trials was performed prior to the actual experiment. The experimental task is summarized in Figure 1. Every trial started with a fixation cross, presented at a random interval between 850 and 1,200 ms. Next, two stimuli were presented to the lower visual field, one to the right and the other to the left. The stimuli could be both chromatic or both achromatic or a combination of one chromatic and one achromatic. After the stimulus presentation, the visibility of one of the stimuli was manipulated using either a visual mask 40 ms after the stimulus onset (Experiment 1) or a TMS pulse 90 ms after the stimulus onset (Experiment 2). In Experiment 1, there were also trials where neither of the stimuli was masked to obtain a baseline for the conscious RTE. The participants were instructed to respond by pressing a gamepad button as fast as they could when they saw a chromatic stimulus or stimuli. The red and the blue stimuli were presented in separate blocks so that the participants knew prior to every block what color they were expected to detect. After the stimulus presentation, they were allowed 1200 ms to respond. During this response period, a blank screen was presented. Next, the participants were asked how many *chromatic* stimuli they saw (none, one, or two) and how confident they were about their number response (confident, quite confident, uncertain, or guessed). The questions and the possible responses were presented on the screen, and the responses were given by pressing gamepad buttons.

In Experiment 1, the participants completed a total of 24 blocks of 20 trials. They performed the reaction task by first using one hand; after half of the blocks were completed, they

changed to the other hand. The red and the blue stimuli were presented in separate blocks, which were done alternately. The starting hand and the order of the stimulus colors were counterbalanced across the participants. In total, 480 trials were completed. In Experiment 2, the participants also finished half of the blocks by using their right hand to perform the reaction task and completed the other half of the blocks by using their left hand. Each hand was used to respond during 6 blocks so that in total, 12 TMS blocks were completed. Each participant had three different stimulation targets in the brain—the left V1, the right V1, and the low center, which served as the control condition (see Section 2.5. TMS). For every stimulation site, the red and the blue stimuli blocks were completed successively for a total of 720 trials. Table 1 presents the number of different trials in the two experiments.

Figure 1. Schematic summary of the experimental procedure. A) Timeline of an experimental trial. The participants' tasks were to press a button as fast as possible when they detected any number of chromatic targets and then to report the number of chromatic stimuli and their degree of confidence in this decision. The visibility of one stimulus was manipulated using visual masking (Exp1) or transcranial magnetic stimulation (TMS) (Exp2). B) Visual fields (functional magnetic resonance imaging mapped) where processing is disturbed by TMS in Experiment 2. Visual processing in the blue dotted area is disturbed by TMS of the right hemisphere and the processing in the red dotted area is disturbed by TMS of the left hemisphere. The control stimulation target disturbed visual processing in the green dotted area, where no stimuli were presented.

Table 1

Number of trials in the experiments. Participants were always presented with two stimuli whose luminance were adjusted so that they were perceived as equally bright.

Experiment	Experiment 1 - Mask						Experiment 2 - TMS					
	No mask		Visual masking				Control		TMS suppression			
Visual manipulation	Neither		Achromatic		Chromatic		Neither		Achromatic		Chromatic	
Target stimulus	Neither		Achromatic		Chromatic		Neither		Achromatic		Chromatic	
Color (per block)	Blue	Red	Blue	Red	Blue	Red	Blue	Red	Blue	Red	Blue	Red
Achromatic stimuli	48	48	24	24	-	-	40	40	40	40	-	-
1 chromatic stimulus	24	24	24	24	24	24	40	40	80	80	40	40
2 chromatic stimuli	24	24	-	-	72	72	40	40	-	-	80	80

2.4. Visual masking (Experiment 1)

In Experiment 1, we manipulated the conscious perception of one of the stimuli using a metacontrast mask. The mask was a black annulus whose inner diameter was the same as the outer diameter of the stimulus that it masked. The outer diameter was 0.21° larger than the stimulus. The mask was presented 40 ms after the stimulus onset for nine frames (75 ms). The mask was presented randomly in either the left or the right stimulus. In Experiment 1, there were also baseline trials where no mask was presented. These trials were used to estimate the conscious RTE using this paradigm.

2.5. Transcranial magnetic stimulation (TMS, Experiment 2)

TMS was delivered using the MagPro X100 stimulator and the model Cool-B65 coil, a liquid cooled 65-mm figure-of-eight coil, both manufactured by MagVenture. TMS intensity was set at 85% of the maximum stimulator output. In our previous studies, performed with the Nexstim stimulator, we used a 65–75% stimulation intensity (Hurme et al., 2017, 2019). Pilot experiments suggested that with the MagPro X100 stimulator, approximately 85% intensity is required to reach equally strong visual suppression as with the Nexstim Eximia stimulator. TMS was delivered 90 ms after the stimulus onset. This stimulus onset asynchrony (SOA)

was selected because it had been the most effective in suppressing conscious perception in our previous studies, and the classical dip around 100-ms SOA (Amassian et al., 1989) has been shown as the most reliable way to suppress conscious perception with TMS (de Graaf et al., 2014).

The stimulation location was based on the individual participants' magnetic resonance imaging (MRI) results using the Localite TMSNavigator 3.0.48 system. The targeted stimulation areas within V1 were defined using retinotopic mapping in fMRI (see *Section 2.6. Magnetic resonance imaging and retinotopic mapping*). For individual participants, the retinotopic locations in their V1, corresponding to the visual field locations where the targets were presented, were the stimulation targets. For all participants, the targets were in the upper bank of the calcarine sulci, in the right hemisphere for the left visual field and vice versa for the right visual field (see Figure 1B). We also included a control target in the visual cortex. The control target was defined anatomically; pulses were delivered to the longitudinal fissure between the lower banks of the calcarine sulci. Consequently, TMS should only affect the upper visual field in the control stimulation, otherwise corresponding to the experimental conditions, where the early visual cortex was stimulated, and the clicking noise and the tactile feedback in the back of the head were similar to the experimental conditions.

2.6. Magnetic resonance imaging and retinotopic mapping

MRI was performed in the Turku PET Center using 3T Philips MRI. For each participant, a high-resolution (voxel size = 1 mm³) T1-weighted anatomical image of the whole head was captured (3D TFE). Visual cortical areas were mapped with fMRI by using a modified version

(Henriksson, Karvonen, Salminen-Vaparanta, Railo, & Vanni, 2012) of the multifocal procedure described by Vanni, Henriksson, and James (2005). The visual stimuli were presented to the scanner using the VisualSystem (NordicNeuroLab, Bergen, Norway) binocular apparatus (800 × 600 resolution) and the Presentation software (Neurobehavioral Systems, Inc., Albany, CA, USA). For the retinotopic mapping, the major imaging parameters were a 1.8-s repetition time, a 3-ms echo time, a 60°-flip angle, a 25-cm field of view, a 96 × 96 matrix, and a 2.5-mm³ voxel size. Twenty-nine slices were acquired in interleaved order. Standard preprocessing with slice-time and motion correction was followed by the estimation of the general linear model with the SPM8 Matlab toolbox.

2.7. Data analysis

Behavioral data was analyzed using R statistical software 3.5.0 (R Core Team, 2018); for Bayesian analyses, we used JASP version 0.8.6 (JASP Team 2018, <https://jasp-stats.org>). Linear mixed-effect models were fitted using the lme4 package (Bates, Mächler, Bolker, & Walker, 2015). The use of mixed-effect models allowed us to take into account the individual differences among the participants as random effects. When selecting the mixed-effect models, we started with the maximum fixed-effect and the random-effect structures. The model with the maximum fixed-effect structure included the following factors: redundant target, stimulus color, and interaction between redundant target and stimulus color. In the second most complex model, the interaction was dropped, and in the simplest model, we only had the redundant target. Random effects were kept maximal as long as the model converged (Barr, Levy, Scheepers, & Tily, 2013). The model with the best Bayesian information criterion (BIC) was selected. In all RTE analyses, the model with the least factors had the lowest BIC, indicating that there were no main effects for the stimulus color or

interactions between the stimulus color and the number of stimuli. In the models, we included only those trials where the participants indicated their confidence in their reported numbers. This decision was made to ensure that only the trials where the participants reported fully conscious or unconscious processing of stimuli would be selected in the analyses. The participants who had trouble detecting the stimuli in the baseline condition (i.e., no visual mask in Experiment 1 and TMS of the control site in Experiment 2) in either of the colors (accuracy of less than .8) were removed from the analyses. Based on these criteria, the data from three participants in Experiment 1 and four participants in Experiment 2 were excluded from the analyses. The data and the R-scripts are available at <https://osf.io/xtqyg/>.

3. Results

3.1. Experiment 1: Visual masking

3.1.1. Response errors

We instructed the participants to respond only when they saw a chromatic stimulus. Therefore, every trial where only achromatic stimuli were presented and the participant responded was considered a response error. The participants erroneously responded to the achromatic-only trials 8% of the time on average ($SD = 6$). This low amount of errors indicated that the participants performed the task as intended.

3.1.2. Effects of visual masking

We plotted the accuracies of the number responses and their confidence intervals (Figure 2A) to examine how effective the metacontrast mask was in suppressing the conscious vision. The mask was not very effective in suppressing the conscious perception when only one chromatic stimulus was presented. However, in approximately half of the critical two-stimulus trials, the participants reported being confident that they saw only one chromatic stimulus. We assume that this difference can be explained by top-down modulation (Ramachandran & Cobb, 1995). When two stimuli are presented and one of them with a metacontrast mask, the unmasked stimulus signal is so strong that it draws attention to it, and the masked stimulus is more likely to be unnoticed. When only one stimulus is presented, the weak signal from the masked stimulus is enough to draw attention to it when no competing stimulus is presented. The mask had little effect on the degree of confidence, as shown in Figure 2B, indicating that visual masking yielded an unequivocal experience of only one stimulus.

Figure 2. Results of Experiment 1. A) The accuracy of the number response in one-stimulus and two-stimulus conditions with blue or red stimulus colors. B) Proportions of the confidence ratings in baseline and masked conditions for both colors (pooled data from one-stimulus and two-stimulus conditions). C) Redundant target effect in baseline and masked (fully unconscious redundant target) conditions for both colors. The baseline here refers to a condition where no mask is presented. Error bars represent bootstrapped 95% confidence intervals.

3.1.3. Redundant target effect (RTE) during conscious perception of stimuli

Because the RTE task used in this study differed from the typical RTE paradigm, we first wanted to demonstrate that our paradigm would produce an RTE when the stimuli were consciously perceived. The RTE that was calculated based on aggregated data (each participant's mean RTE) can be found in Figure 2C. The final model with the best BIC included fixed and random effects for the redundant target. As shown in Table 2, the consciously perceived redundant target speeded up the reaction times by 23 ms on average (by participant SD = 9 ms, as indicated by the corresponding random effect).

Table 2

Results of the linear mixed-effect model for the conscious RTE baseline

	Fixed effects			Random effects
	Estimate ms	95% CI	T-value	SD
Intercept	285.68	271.40 - 304.67	35.11	31.84

3.1.4. RTE with an unconscious redundant target (visual masking)

We wanted to find out if the participants could unconsciously process the redundant stimulus, whose perception was disturbed by visual masking. We compared the reaction times between the confidently and correctly perceived one chromatic-stimulus trials and

the reaction times in the trials where two chromatic stimuli were presented, but the participants reported being confident (highest confidence rating) that they saw only one. This left us with 82 (SD = 42) trials per participant on average (on average, 19 with one blue stimulus, 22 with two blue stimuli, 18 with one red stimulus, and 23 with two red stimuli). Importantly, in the one-stimulus condition, in addition to the chromatic target stimulus, a redundant *gray* stimulus, which was subjectively evaluated equally bright as the chromatic stimulus, was masked. The participants' subjective experience was therefore the same in both situations, and the only difference between those two conditions was the color (chromatic or achromatic) of the masked redundant stimulus. The aggregated RTEs are presented in Figure 2C. The mixed-effect model with the best BIC included fixed and random effects for the redundant target. The results are presented in Table 3. The unconsciously perceived redundant chromatic target speeded up the reaction times by 18 ms on average.

Table 3

Results of the linear mixed-effect model for the unconscious RTE (masked)

	Estimate ms	Fixed effects			Random effects
		95% CI	T-value		SD
Intercept	288.03	271.40 - 304.67	33.94		32.84
Redundant target	-17.65	-26.77 - -8.54	-3.80		7.61

3.2. Experiment 2: TMS

3.2.1. Response errors

The participants erroneously responded to the achromatic stimuli only 7% of the time on average (SD = 5), indicating that the participants did the task as instructed.

3.2.2. TMS suppression

We plotted the accuracies of the number responses and their confidence intervals (Figure 3A) to visualize the strength of TMS suppression of vision. As with visual masking (Experiment 1; Figure 2), the suppressive effect was larger in the two-stimulus trials. Compared with Experiment 1 (Figure 2A), the suppression in the one-stimulus trials was more effective when using TMS than when using the metacontrast mask.

Figure 3. Results of Experiment 2. A) The accuracy of the number response in one-stimulus and two-stimulus conditions with blue or red stimulus colors. B) Proportions of the confidence ratings in TMS baseline and TMS disturbance conditions for both colors (pooled data from one-stimulus and two-stimulus conditions). C) Redundant target effect in TMS baseline and TMS disturbance conditions for both colors. Error bars represent bootstrapped 95% confidence intervals.

3.2.3. RTE baseline under TMS

To obtain a baseline for the RTE in Experiment 2 where TMS was applied, we analyzed the data where the control area in the early visual cortex was stimulated (Figure 1B). We refer

to this experimental condition as TMS baseline. The RTE (calculated from aggregated data, mean per participant) in the baseline TMS condition is presented in Figure 3C, and the distribution of the confidence levels is presented in Figure 3B. In the RTE analyses, we included only those trials where the participants indicated being confident in their reported numbers (highest rating). The final mixed-effect model, selected using the BIC, included fixed and random effects for the redundant target. As shown in Table 4, the consciously perceived redundant target during which TMS was applied to the control area in the visual cortex speeded up the reaction times by 17 ms on average.

Table 4

Results of the linear mixed-effect model for the conscious RTE baseline under TMS

	Fixed effects			Random effects
	Estimate ms	95% CI	T-value	SD
Intercept	349.85	309.34 - 390.36	16.93	76.87
Redundant target	-16.93	-24.15 - -9.71	-4.60	6.95

3.2.4. RTE when the redundant target is suppressed by TMS of V1

Finally, we investigated whether we could find an unconscious RTE with a color stimulus whose conscious visibility had been suppressed by TMS of V1. We call this experimental condition TMS disturbance condition. The distribution of the confidence in the number response can be found in Figure 3B, and the RTEs (calculated from aggregated data) for both stimulus colors are shown in Figure 3C. In the analysis, only those trials where the participants were confident (highest confidence rating) of their number responses and reported seeing only one chromatic stimulus were included. This left us with 156 (SD = 43) trials per participant on average (on average, 60 with one blue stimulus, 21 with two blue stimuli, 56 with one red stimulus, and 16 with two red stimuli). The best-fitting mixed-effect

model was again the one with the least factors, where the response time to a chromatic stimulus was explained by the redundant target. The results are presented in Table 5. When V1 activity was suppressed using TMS, the redundant chromatic target did not speed up the reaction times. The Bayesian paired sample t-tests for the aggregated means with the uninformative Cauchy prior (scale = 0.707) showed significant evidence for the null hypothesis in both red ($BF_{10} = 0.27$) and blue ($BF_{10} = 0.28$) unconscious RTEs.

Table 5

Results of the linear mixed-effect model for the unconscious RTE (TMS suppressed)

	Fixed effects			Random effects
	Estimate ms	95% CI	T-value	SD
Intercept	342.42	297.66 - 387.18	14.99	85.18
Redundant target	2.55	-7.17 - 12.28	0.51	11.65

3.2.5. Direct comparison of unconscious processing in Experiments 1 and 2

To compare the magnitude of unconscious processing in the two experiments directly we conducted a mixed-effects model including the conscious one chromatic stimulus trials and trials with suppressed chromatic redundant target from both experiments. In our model, the intercept represents reaction times to one consciously perceived stimulus. As shown in Table 6, unconscious redundant target speeded up reaction times in Experiment 1, but in Experiment 2 this effect was absent as indicated by the significant interaction between unconscious redundant target and Experiment 2. Participants were also significantly slower, 62 ms on average, to respond in the TMS experiment.

Table 6

Results of the linear mixed effects model for the unconscious RTE

	Fixed effects			Random effects

Redundant target × Exp 2	19.48	1.72	- 37.25	2.15	

4. Discussion

In this study, we demonstrated that unconscious processing of chromatic information from long- and short-wavelength stimuli can influence behavior (Experiment 1), but this effect is eliminated when TMS is targeted to V1 (Experiment 2). Unconscious processing was measured using the RTE, that is, speeding up the reaction times when two stimuli were presented instead of one. We found an RTE with both colors when the perception of the color of the redundant stimulus was disturbed by a visual mask. However, when conscious perception of the color of the redundant stimulus was suppressed using TMS, the unconscious RTE was absent. This result suggests that the unconscious chromatic RTE depends on early visual cortex in neurologically healthy participants. While TMS was targeted retinotopically to V1 specifically, we cannot rule out the possibility that the corresponding retinotopic locations in V2 and possibly also V3 were also activated by TMS. Instead, our results demonstrate that the subcortical (LGN, SC) to extrastriate pathways (e.g. V4, V5) are not sufficient to produce blindsight-like processing of chromatic information in neurologically healthy observers.

We argue that more generally, converging empirical evidence strongly suggests that all processing (not just unconscious processing) of chromatic stimuli depends on the early visual cortex (possibly V1 selectively) in neurologically healthy humans. Our results are in line with previous studies that have found that unconscious processing of chromatic

information depends on early visual cortex in neurologically healthy individuals when subliminal priming or forced-choice methodology (Railo, Salminen-Vaparanta, Henriksson, Revonsuo, & Koivisto, 2012) or RTE is used (Railo et al., 2014). Therefore, it seems likely that the unconscious color RTE observed in patients with blindsight (Tamietto et al., 2010) cannot be generalized to neurologically healthy individuals. Furthermore, another blindsight study found no unconscious chromatic RTE with short-wavelength or long-wavelength stimuli, indicating that the chromatic RTE is not consistently observed in blindsight, either (Marzi et al., 2009).

It may be argued that the unconscious RTE indexes a highly specific type of unconscious processing; that our findings do not rule out the possibility of other kinds of chromatic blindsight-like behaviors of neurologically healthy observers. There are two possible explanations for the RTE—neural coactivation and the race model (Miller, 1982)—but both rely heavily on fast responses. According to the race model, RTE is explained by two signals competing to produce a response that is more efficient compared with one signal. When two signals are presented, the participant responds as soon as either of those signals exceeds the response threshold; therefore, faster responses are more likely. In contrast, the neural coactivation model explains RTE when the race model is violated. It means that the speeding up cannot be explained by the distribution of the reaction time in response to a single stimuli. The responses to two stimuli are faster than those that could be produced by those two stimuli independent of each other; therefore, it provides evidence for neural coactivation. Either way, RTE depends on fast automatic responses. It could thus be argued that the unconscious processing of chromatic information without V1 is too slow to produce RTE in neurologically healthy participants. However, again, the conclusion is that the

unconscious processing of color information by neurologically healthy participants differs from the unconscious processing by patients with blindsight, as reported in the study of Tamietto et al. (2010), who found blindsight even when using the chromatic RTE paradigm.

What is known about the unconscious processing of chromatic information in paradigms in which TMS of early visual cortex is used and no speeded response is required? An early study using a forced-choice paradigm reported unconscious processing of color information by neurologically healthy observers when the chromatic stimulus was suppressed by TMS of early visual cortex (Boyer et al., 2005). However, there are two methodological shortcomings in this study. First, the study did not apply neuronavigated TMS to V1 but a trial-and-error method to find a location in the occipital cortex where TMS suppresses conscious perception. Because V2 and V3 areas are often closer to the scalp than the corresponding visual field locations in V1, the trial-and-error approach is more likely to stimulate V2 or even V3 than V1 (Salminen-Vaparanta, Noreika, Revonsuo, Koivisto, & Vanni, 2012; Thielscher, Reichenbach, Uğurbil, & Uludağ, 2010). Even when TMS targeting is based on retinotopic mapping, V1 will likely not be *selectively* suppressed, and V2 representation is probably influenced to some degree and even V3 might be affected (Salminen-Vaparanta, Noreika, Revonsuo, Koivisto, & Vanni, 2012). If the geniculostriate visual pathway through V1 is necessary for unconscious visual processing, then TMS studies that do not suppress vision by neuronavigated stimulation of V1 may observe blindsight-like behavior because they fail to sufficiently disturb the V1 activity (and instead suppress V2 or V3). fMRI-based neuronavigated TMS that is targeted specifically to V2 is known to suppress visual awareness (Salminen-Vaparanta, Koivisto, Noreika, Vanni, & Revonsuo, 2012). In addition, neuronavigated TMS of V3 interferes with visual awareness, but to a lesser extent

as compared with TMS targeted to V2 (Salminen-Vaparanta, Koivisto, Vorobyev, Alakurtti, & Revonsuo, 2019). Therefore, future studies should examine if blindsight-like behavior is more likely observed when TMS suppression is produced by the neuronavigated stimulation of V2 or V3 compared to V1 stimulation.

The second factor that could explain the unconscious processing of chromatic information, as found by Boyer et al. (2005), is their use of a dichotomous seen-unseen consciousness rating that is known to produce false-positive findings. Dichotomous reports are likely to overestimate the amount of unconscious trials (Loyd, Abrahamyan, & Harris, 2013; Mazzi, Bagattini, & Savazzi, 2016; Overgaard, 2011). Railo et al. (2012) measured unconscious processing of chromatic information using a stricter four-step rating scale. Unconscious processing of color information was found when the participants reported seeing something but could not identify the color. However, when they reported being fully unaware of the stimulus (lowest rating), no unconscious processing of color information was found with either the forced-choice or the priming methodology. These results, together with the present findings, suggest that the above-chance response accuracy reported by Boyer et al. (2005) was observed due to the dichotomous awareness rating and was, in fact, a decision based on degraded awareness rather than completely unconscious perception. In the present study, the participants reported only the number of the *chromatic* stimuli; thus, they possibly retained some residual vision of the stimulus presence (independently of its color). However, in the majority of the trials, the perception of the whole stimulus (not just its color) was most likely suppressed. For instance, in a previous study, we employed a similar paradigm to suppress the visibility of the stimulus completely (Hurme et al., 2017). In the present study, we used a four-point confidence scale so that in the trials where the

participants reported being confident about their number answers, they were certain that there were no more or less chromatic stimuli than they indicated. All trials where participants reported not being confident about their indicated number of chromatic stimuli were excluded from the analyses.

Two previous TMS studies have used the S-cone paradigm (Allen, Sumner, & Chambers, 2014; Railo et al., 2014). Railo et al. (2014) did not find unconscious processing using S-cone isolating stimuli or L/M-cone isolating stimuli when they suppressed perception using TMS of V1. However, as discussed in the introduction, they failed to demonstrate that unconscious processing of color information was possible with their stimuli when no TMS was applied. Therefore, it might be that their experiment was just insensitive to unconscious processing of color information. Allen et al. (2014) found that they could disturb the conscious perception of both S-cone and achromatic contrast arrow stimuli using TMS of the early visual cortex, while the accuracy of discriminating the arrow was above the chance level. Based on this result, the authors concluded that they had found TMS-induced blindsight. However, while the result of the study of Allen et al. (2014) could reflect “relative blindsight”—in the sense that it showed a decrease in subjective visibility without a concurrent decrease in objective performance (Lau & Passingham, 2006)—it differs from the present study in one key aspect. We aimed to use TMS to mimic blindsight in the sense that the V1 activity would be disturbed to the degree that conscious vision would be eliminated. Allen et al. (2014) calibrated the stimuli so that the participants could detect the stimuli only in approximately half of the trials when no TMS was applied. TMS only slightly further decreased the visibility of the stimuli, but in most trials, the stimuli were not unconscious due to TMS (but due to the stimulus being so low-contrast). Allen et al. could not separate

the trials that were unconscious due to TMS from those that were unconscious just because the stimuli were weak to begin with. In contrast, we made the task relatively easy in the baseline condition (without TMS) and specifically used TMS to suppress the visibility of the targets.

One limitation of all TMS studies is that the activation that is induced in the brain under the coil spreads to other areas that are connected to the stimulated area (Ilmoniemi et al., 1997). Therefore, it could be argued that the effect of TMS is not because of the disruption in the directly stimulated area but is due to the activations in the connected areas.

However, in a similar fashion, local cortical lesions can also lead to neuronal changes in distantly connected regions of the brain (Sprague, 1966). Furthermore, while retinotopic mapping enabled us to target TMS pulses to the retinotopically correct region of V1, this does not mean that we *selectively* stimulated V1. A significant electric field could also have been induced in other nearby visual areas, most importantly V2 and V3 (Salminen-Vaparanta et al., 2012). While this raises a question whether TMS-induced blindsight and blindsight are comparable, one should note that lesions in blindsight patients are not restricted to V1 either, but also spans other areas of the early visual cortex. For example, in the frequently studied blindsight patient G.Y. the lesion “extends not only into the peripheral representation of V1 but also into the peripheral representations of ventral extrastriate areas V2v, V3v, and V4v” (Baelser, Morland, & Wandell, 1999). In addition, G.Y. has a parietal lesion (Baelser, Morland, & Wandell, 1999). Notably, this patient G.Y. nevertheless shows chromatic blindsight (Brent, Kennard, & Ruddock, 1994). In chromatic RTE task, there was significant increase in BOLD-activation during blindsight in G.Y.’s SC and posterior superior temporal region (Tamietto, et al., 2010), suggesting that the SC to V5

connections might be critical for chromatic blindsight. On the other hand, Ajina and Bridge have proposed that LGN to V5 might be the important pathway in blindsight (2018; 2019). Both SC and LGN have been found being important in blindsight in primate studies (Schmid, et al., 2010; Kato, Takaura, Ikeda, Yoshida, & Isa, 2011). Although studies in non-human primates allow for more precise manipulation of brain regions (e.g. through lesioning), conclusions about the roles of different visual areas are still difficult. For instance, Kinoshita et al. (2019) note that different findings between lesion-studies on non-human primates could be explained by whether the produced lesion in V1 is restricted to gray matter, also includes white matter, or extends to V2. The most obvious shortcoming of any blindsight study is the failure to properly interfere with V1. Studies on monkeys show that V2 and V3 activity depend strongly on input from V1 as inactivation or lesion of V1 diminishes V2 and V3 activity (Girard & Bullier, 1989; Girard, Salin, & Bullier, 1991; Schmid, Panagiotaropoulos, Augath, Logothetis, & Smirnakis, 2009). In contrast, inactivation of areas V2 or V3, which provide corticocortical feedback to V1, have a clearly weaker effect on V1 activity (Sandell & Schiller, 1982; Nassi, Lomber, & Born, 2013). Thus, we conclude that the most parsimonious explanation for the present finding is that the suppression of conscious and unconscious vision is due to changes in V1 activity, even though the contribution of V2 (or V3) cannot fully be dismissed. Moreover, the control TMS condition was specifically chosen to control for potential network effects. The control stimulation site was V1, but instead of the upper bank of the V1, we stimulated its lower bank (i.e., V1 but in different receptive field locations). This approach is superior to using a sham stimulation condition (which may feel different to the participant and elicits very weak cortical activations) or a more distant control site, such as the vertex (which feels very different to the participant and activates clearly different networks of brain areas than those in the experimental condition).

A difference between the present study and many studies on patients with blindsight is that we used small stimuli with brief presentation durations. This was done to ensure sufficiently strong suppression by TMS. Studies on patients typically use large stimuli. It thus remains possible that larger and longer-duration stimuli could be more effective in activating neurons in the SC, thereby enabling unconscious chromatic processing. Nonetheless, although SC has large receptive fields, it is sensitive to very small and brief stimuli (Cynader & Berman, 1972). Wurth, Richmond, and Judge (1980) showed that monkey SC strongly responded to a 5 ms flash (stimulus size = $0.5 \times 1.0^\circ$). Schiller, Stryker, Cynader, and Berman (1974) demonstrated that a 0.3° flash produced strong activation in monkey SC (stimulus duration = 1 s) when the V1 activity was suppressed by cooling. Furthermore, monkeys with V1 lesions manifest blindsight-like behavior in response to small and briefly presented stimuli (Mohler & Wurtz, 1977), and human patients with blindsight can unconsciously process small and brief stimuli (e.g., Savina & Guitton [2018] used a 0.5° stimulus with an 86-ms duration). We have also previously shown that RTE can be observed when similar small and brief achromatic contrast stimuli were suppressed by TMS of V1 at a 90 ms SOA (Hurme et al., 2017). Based on these findings, we suggest that stimulus intensity is likely not the reason why we did not find unconscious chromatic processing, although this question should be directly addressed in future studies. Another minor shortcoming with our stimuli was that the subjective brightness was matched using heterochromatic flicker fusion task in which a stimulus was presented in the center of the visual field even though the stimuli in the experiment were presented 2° from the fixation cross. The perceived brightness of the stimuli might have been slightly different in the calibration location than in the location in which the stimulus was presented in the experiment. However, this issue is negligible because the task was to detect chromaticity, not luminance.

To conclude, in neurologically healthy observers unconscious processing of both short- and long-wavelength chromatic stimuli is possible but not without the early visual cortex, possibly specifically the V1.

Journal Pre-proof

Highlights

- Stimulus color was suppressed by visual masking or transcranial magnetic stimulation
- Unconscious processing was observed when visual mask was used
- Unconscious processing was absent when TMS to V1 was used
- Unconscious processing of chromaticity depends on early visual cortex

Author contribution statement

- M.H. designed the study, programmed the experiment, collected the data, performed the analyses and wrote the majority of the manuscript,
- M.K. participated in planning the experiment, provided help with the analyses and revised the manuscript
- L.H. provided assistance with retinotopic mapping and fMRI, and revised the manuscript.
- H.R. helped designing the study, participated in the analyses and wrote a part of the manuscript.
