Abstract—A small-signal model is derived for saturated induction machines. Inductances are allowed to saturate as a function of their own current (or flux), and the mutual saturation effect originating mainly from skewed or closed rotor slots is also included in the model. The model fulfills the reciprocity conditions, and it can be applied to parameter identification and to the analysis and development of flux angle estimation methods. As application examples, the parameters of a 2.2-kW induction machine were identified using the data obtained from time-stepping finite-element analysis and locked-rotor measurements. The proposed model fits well to the data, and the fitted parameters are physically reasonable.

Index Terms—Closed slots, induction motors, magnetic saturation, motor models, reciprocity, rotor skew, signal injection.

I. INTRODUCTION

Induction machines are usually magnetically saturated in the rated operating point. Conventionally, the main flux is assumed to saturate only as a function of the magnetizing current. However, it has been observed that the main flux may depend significantly on the load [1], [2]. This mutual saturation effect originates mainly from skewed and closed rotor slots [3], which are used in the majority of small machines.

Magnetic saturation affects the transient behavior of the machine, but the effects of saturation are not well known. For example, the dynamical effects of saturation are usually ignored in parameter identification methods that rely on transient behaviour [4]. Consequently, incremental parameters may be unintentionally identified in practical saturated conditions instead of the expected steady-state parameters. Other examples are various flux estimation methods based on saturation-induced spatial anisotropies, e.g. [5], [6]. Conventionally, heuristic high-frequency small-signal models are applied in the analysis of these methods. Saturation-induced anisotropies depend on the load and flux level, and they are generally not fixed in position relative to any flux component [7].

The small-signal impedance of a saturated machine depends on the direction of the excitation signal [8]; this phenomenon has been modeled assuming that the main flux depends only on the magnetizing current [9], [10]. However, the saturation phenomena specific to machines with closed or skewed rotor slots are more complicated, and this assumption should be relaxed.

It is common practice to consider the losses dissipated in the magnetic circuit separately, and to use lossless inductors to model the magnetic circuit as in Fig. 1. The saturable magnetic circuit should fulfill the reciprocity conditions [11], [12] since otherwise the magnetic circuit may unintentionally behave as an energy source or sink. In other words, the energy stored in the magnetic circuit should be independent of the integration path. When relaxing the assumptions relating to the saturation, these conditions have to be taken into account.

This paper presents a small-signal model suitable for saturated induction machines that may have closed or skewed rotor slots. Each inductance is allowed to saturate as a function of its own current (or flux), and the mutual saturation effect is also included in the model. The proposed model fulfills the reciprocity conditions. As an example, the model is applied to parameter identification of a 2.2-kW induction machine. The identification data is produced using time-stepping finite-element analysis (FEA) [13] and locked-rotor measurements. Voltage pulses [14] and pulsating voltage-signal injection are used as excitation signals.

II. MACHINE MODEL

Vectors will be denoted by boldface lowercase letters and matrices by boldface uppercase letters. The matrix transpose will be marked with the superscript T. The identity matrix, the orthogonal rotation matrix, and the zero matrix are

\[
I = \begin{bmatrix}
1 & 0 \\
0 & 1
\end{bmatrix}, \quad J = \begin{bmatrix}
0 & -1 \\
1 & 0
\end{bmatrix}, \quad O = \begin{bmatrix}
0 & 0 \\
0 & 0
\end{bmatrix}
\]

respectively. Incremental inductances will be marked with the subscript t.

A. Large-Signal T Model

In a general coordinate system rotating at angular speed \(\omega_s\), the voltage equations of the induction machine are

\[
\frac{d\psi_s}{dt} = u_s - R_s i_s - \omega_s J \psi_s
\]
\[
\frac{d\psi_r}{dt} = u_r - R_r i_r - (\omega_s - \omega_m) J \psi_r
\]
B. Power Balance

For per-unit quantities, the power balance is obtained from (2) as

\[ i^T \mathbf{u}_s + i^T \mathbf{u}_r = R_s i_s^2 + R_r i_r^2 + \frac{dW_i}{dt} + T_e \omega_m \]  

where \( i_s = \| \mathbf{i}_s \| \) and the magnitudes of other vectors are denoted similarly. The electromagnetic torque is

\[ T_e = \psi_s^T \mathbf{J}_r = i_s^T \mathbf{J} \psi_s \]  

and the rate of change of the magnetic energy is

\[ \frac{dW_i}{dt} = i_s^T \frac{d\psi_s}{dt} + i_r^T \frac{d\psi_r}{dt} \]

\[ = i_s \frac{d\psi_{s\sigma}}{dt} + i_m \frac{d\psi_m}{dt} + i_r \frac{d\psi_{r\sigma}}{dt} \]  

The last form is obtained by assuming the flux vectors to be parallel with the corresponding current vectors in accordance with Fig. 1, while the inductances may be functions of the currents or fluxes. Based on (6), the incremental inductances should fulfill the reciprocity conditions [12]:

\[ \frac{\partial \psi_{s\sigma}}{\partial i_m} = \frac{\partial \psi_m}{\partial i_s}, \frac{\partial \psi_m}{\partial i_r} = \frac{\partial \psi_{r\sigma}}{\partial i_m}, \frac{\partial \psi_{r\sigma}}{\partial i_s} = \frac{\partial \psi_m}{\partial i_r} \]  

The reciprocity conditions are given in a more general form in Appendix A.

C. Assumptions on Magnetic Saturation

In the following, \( L_{r\sigma} \) is assumed constant for simplicity, but \( L_m \) and \( L_r \) are functions of two currents:

\[ L_m(i_m, i_r) = \frac{\psi_m(i_m, i_r)}{i_m}, \quad L_r(i_m, i_r) = \frac{\psi_r(i_m, i_r)}{i_r} \]  

(cf. illustration in Fig. 2 relating to \( L_m \)). The following incremental inductances fulfilling (7) are defined:

\[ L_{m0} = \frac{\partial \psi_m}{\partial i_m}, \quad L_{r\sigma} = \frac{\partial \psi_{r\sigma}}{\partial i_m}, \quad L_t = \frac{\partial \psi_m}{\partial i_r} = \frac{\partial \psi_{r\sigma}}{\partial i_r} \]  

Assuming the magnetizing current magnitude \( i_m \) constant, the magnitude \( \psi_m \) of the main flux decreases as the magnitude \( i_r \) of the rotor current increases. Hence, the incremental mutual inductance \( L_t \) is negative. If needed, the saturation of \( L_{r\sigma} \) could be easily taken into account.

III. LINEARIZED MODEL

A. Preliminaries

In the following, tildes refer to the deviation about the operating point and operating-point quantities are marked with the subscript 0, e.g., \( \mathbf{u}_s = \mathbf{u}_s - \mathbf{u}_{s0} \). Synchronous coordinates rotating at constant angular speed \( \omega_{s0} \) are considered. The linearized voltage equations are

\[ \frac{d\tilde{\mathbf{u}}_s}{dt} = \tilde{\mathbf{u}}_s - R_s \tilde{i}_s - \omega_{s0} \mathbf{J} \tilde{\psi}_s \]  

\[ \frac{d\tilde{\mathbf{u}}_r}{dt} = \tilde{\mathbf{u}}_r - R_r \tilde{i}_r - \omega_{s0} \mathbf{J} \tilde{\psi}_r + \mathbf{J} \psi_{r0} \tilde{\omega}_m \]  

where the operating-point angular slip frequency is \( \omega_{r0} = \omega_{s0} - \omega_{s0} \). The deviations of the stator and rotor fluxes are

\[ \tilde{\psi}_s = L_{s0} \tilde{i}_s + L_{m0} \tilde{i}_r + i_{m0} L_m \]  

\[ \tilde{\psi}_r = L_{m0} \tilde{i}_s + L_{r0} \tilde{i}_r + i_{m0} L_m + i_{r0} L_{r\sigma} \]  

respectively. The linearized torque expression is

\[ \tilde{T}_e = \psi_{r0}^T \mathbf{J}_r - i_{r0}^T \mathbf{J} \tilde{\psi}_r \]
The deviation of the magnetizing inductance can be written as
\[\tilde{L}_m = \left( \frac{\partial L_m}{\partial x_m} \right)_{0} \tilde{x}_m + \left( \frac{\partial L_m}{\partial x_m} \right)_{0} \tilde{x}_m + \left( \frac{\partial L_m}{\partial t_r} \right)_{0} \tilde{t}_r + \left( \frac{\partial L_m}{\partial t_q} \right)_{0} \tilde{t}_q \]  
\[= \frac{L_{m0} - L_m}{L_{m0}} \tilde{x}_m + \frac{L_{t0}}{L_{m0}} \tilde{t}_r \quad (13)\]
where \(\tilde{x}_m = \tilde{i} + \tilde{i}_r\). Assuming no mutual saturation effect, i.e. \(L_{t0} = 0\), the deviation \(\tilde{L}_m\) of the magnetizing inductance is zero if the current deviation \(\tilde{t}_m\) is perpendicular to the operating-point current \(i_{m0}\). The deviation of the rotor leakage inductance \(L_{r0}\) can be derived in a fashion similar to (13).

**B. State-Space Representation**

The deviations of the inductances \(\tilde{L}_m\) and \(\tilde{L}_{r0}\) can be inserted into (11). Furthermore, \(\tilde{i}_s\) and \(\tilde{i}_r\) can be solved from (11) and inserted into (10), leading to a linear multiple-input-state-space representation
\[\frac{d\tilde{x}}{dt} = A\tilde{x} + B_s\tilde{u}_s + B_r\tilde{u}_r + b\tilde{w}_m\]  
\[\tilde{x} = \begin{bmatrix} \tilde{\psi}_s \\ \tilde{\psi}_r \end{bmatrix}, \quad B_s = \begin{bmatrix} I \\ 0 \end{bmatrix}, \quad B_r = \begin{bmatrix} 0 \\ I \end{bmatrix}, \quad b = \begin{bmatrix} 0 \\ 0 \end{bmatrix}\]  
(14)
The state matrix is
\[A = \begin{bmatrix} R_s I & O \\ O & R_r I \end{bmatrix} L^{-1} - \begin{bmatrix} \omega_0 J & O \\ O & \omega_{r0} J \end{bmatrix}\]  
(16)
where the inductance matrix is defined as
\[L = \begin{bmatrix} L_{s0} I & L_{m0} I \\ L_{m0} I & L_{r0} I \end{bmatrix} + \begin{bmatrix} L_{m0} - L_{t0} \\ L_{r0} - L_{r0} \end{bmatrix} \begin{bmatrix} i_{m0} T_0 \\ i_{m0} T_0 \end{bmatrix} \]  
(17)
The matrix \(L\) is symmetric due to the reciprocity conditions, and its last three terms originate from saturation.

The stator current, the rotor current, and the torque are chosen as output variables,
\[\tilde{i}_s = C_s \tilde{x}, \quad \tilde{i}_r = C_r \tilde{x}, \quad \tilde{T}_e = c\tilde{x}\]  
(18)
where the output matrices relating to the currents are
\[C_s = \begin{bmatrix} I & O \end{bmatrix} L^{-1}, \quad C_r = \begin{bmatrix} O & I \end{bmatrix} L^{-1}\]  
(19)
and the output matrix relating to the torque
\[c = \psi_{r0}^T \begin{bmatrix} O & J \end{bmatrix} L^{-1} - \psi_{r0}^T \begin{bmatrix} O & J \end{bmatrix}\]  
(20)
in accordance with (12). The system can easily be analyzed using conventional tools for linear systems. If the saturation is not taken into account (i.e. \(L_{m0} = L_{m0}, L_{r0} = L_{r0}\), and \(L_{t0} = 0\)), the small-signal model equals the conventional space-vector model. The model presented in [10] is obtained as a special case by choosing \(L_{r0} = L_{r0}\) and \(L_{t0} = 0\).

**C. Steady-State Relations**

From (2) and (3), the steady-state condition
\[\begin{bmatrix} u_{s0} \\ u_{r0} \end{bmatrix} = \begin{bmatrix} R_s I + \omega_0 L_{s0} J \\ \omega_0 L_{r0} m_0 J \end{bmatrix} \begin{bmatrix} i_{s0} \\ i_{r0} \end{bmatrix}\]  
(21)
is obtained. The operating-point voltages can thus be determined if the parameters and the operating-point currents are known.

In many applications, the stator voltage \(u_{s0}\), the stator current \(i_{s0}\), and the stator angular frequency \(\omega_0\) are known in the operating point. Furthermore, the rotor winding is typically short-circuited, and the rotor current \(i_{r0}\) is inaccessible. Therefore, it is useful to solve the rotor current from (21),
\[i_{r0} = -J \begin{bmatrix} u_{s0} - (R_s I + \omega_0 L_{s0}) i_{s0} \end{bmatrix} / (\omega_0 L_{m0})\]  
(22)
Hence, the magnetizing current \(i_{m0} = i_{s0} + i_{r0}\) and the rotor flux \(\psi_{r0} = L_{m0} i_{s0} + L_{r0} i_{r0}\) needed in the linearized model can be calculated.

In addition to \(i_{r0}\), two parameters can be solved from (21). Convenient choices are the rotor resistance and the rotor inductance:
\[R_r = i_{r0}^T (u_{s0} - \omega_0 L_{m0} i_{s0}) / i_{r0}^2\]  
(23)
\[L_{r0} = -i_{r0}^T J (u_{s0} - \omega_0 L_{m0} i_{s0}) / (\omega_0 i_{r0}^2)\]  
(24)
The rotor leakage inductance needed in the model is \(L_{r0} = L_{r0} - L_{m0}\). If the linearized model is used for parameter estimation or fitting, the information in (21) should be used to avoid inconsistency with the operating-point data. Furthermore, the fitting procedure becomes easier, since the number of independent parameters decreases. If the operating-point stator voltage \(u_{s0}\) is unknown, it may be useful to express the rotor current as
\[i_{r0} = (\alpha_0 I + \omega_0 J)^{-1} (u_{s0} - \omega_0 L_{m0} i_{s0}) / L_{r0}\]  
(25)
where \(\alpha_0 = R_r / L_{r0}\) is the inverse rotor time constant.

**IV. TRANSFER FUNCTIONS**

The stator current can be expressed as \(\tilde{i}_s(s) = Y_s(s)\tilde{u}_s(s)\), where the multiple-input-multiple-output transfer function matrix (or the small-signal stator-admittance matrix) is
\[Y_s(s) = \begin{bmatrix} Y_{sd}(s) \\ Y_{dq}(s) \end{bmatrix}\]  
(26)
where \(L_4\) is a 4x4 identity matrix. The expression (26) is valid in any synchronous coordinates. An admittance matrix \(Y_s(s)\) can be represented in new synchronous coordinates as
\[Y_s'(s) = e^{j\theta_0} J Y_s(s) e^{-j\theta_0} J\]  
(27)
where \(\theta_0\) is the angle of the d axis of original coordinates in new coordinates. The coordinate transformation matrix can be expressed as \(e^{j\theta_0} J = \cos(\theta_0) I + \sin(\theta_0) J\). In the case of no saturation, \(Y_s(s) = Y_{sd}(s) I + Y_{dq}(s) J = Y_s'(s)\) holds, and the admittance matrix does not depend on the angle \(\theta_0\).
In the unsaturated case, the system could be expressed as a complex-valued single-input-single-output transfer function for complex-valued space vectors.

When the stator current is considered as the input of the system, the reciprocal relationship \( \tilde{u}_i(s) \simeq Z_s(s)\tilde{i}_s(s) \) can be used, where the small-signal stator-impedance matrix is \( Z_s(s) = Y_{s}^{-1}(s) \). If the saturation is not taken into account, the stator-impedance matrix reduces to the well-known expression

\[
Z_s(s) = R_\sigma s + (sI + \omega_m) L_\sigma - k_{t0}^2 R_t (\alpha_0 I - \omega_m) (sI + \alpha_0 I + \omega_m) - 1
\]

where the total leakage inductance and the total resistance are

\[
L_\sigma = L_{\sigma 0} + k_{t0} L_{\tau 0}, \quad R_\sigma = R_s + k_{t0}^2 R_t
\]

respectively, and \( k_{t0} = L_{\mu 0}/L_{\tau 0} \) is the magnetic coupling factor of the rotor.

If torsional dynamics are of interest [15], [16], the transfer function from the rotor speed to the electromagnetic torque is needed. The electromagnetic torque can be expressed as \( T_e(s) = G(s)\omega_m(s) \), where the single-input-single-output transfer function is

\[
G(s) = c(sI - A)^{-1} b
\]

In a fashion similar to (26) and (30), other transfer-function matrices can be obtained using (14) and (18).

V. REDUCED-ORDER STATOR IMPEDANCE

A short-circuited rotor winding is considered here, i.e. \( \tilde{u}_r = [0, 0]^T \). At higher frequencies, the stator-impedance matrix can be approximated as

\[
Z_s(s) = R_\sigma(s) + (sI + \omega_m) L_\sigma \quad (31)
\]

where \( L_\sigma \) is the total leakage inductance matrix and \( R_\sigma \) is the total resistance matrix. The derivation of (31) and the expressions for \( L_\sigma \) and \( R_\sigma \) are given in Appendix B.

The effects of the rotor leakage inductance saturation are more prominent at high frequencies while the saturation of the magnetizing inductance mainly affects at low frequencies. Omitting the saturation of the magnetizing inductance and the effect of the main flux on the rotor leakage inductance as well, i.e. \( L_{\mu 0} = L_{\mu 0} \) and \( L_{\tau 0} = 0 \), yields

\[
L_\sigma = L_{\sigma 0} + (sR_{\sigma 0} - L_{\sigma 0}) \frac{L_{\tau 0}^{-1}}{L_{\tau 0}^{-1}}
\]

\[
R_\sigma = R_{\sigma 0} + (sR_{\sigma 0} - R_{\sigma 0}) \frac{L_{\tau 0}^{-1}}{L_{\tau 0}^{-1}}
\]

where \( \theta_0 \) is the angle of the operating-point rotor current vector. The incremental total leakage inductance and the incremental total resistance are

\[
L_{\sigma 0} = L_{\sigma 0} + k_{t0} L_{\tau 0}, \quad R_{\sigma 0} = R_s + k_{t0}^2 R_t
\]

respectively, where \( k_{t0} = L_{\mu 0}/(L_{\mu 0} + L_{\tau 0}) \). It is worth noticing that both the total leakage inductance matrix and the total resistance matrix depend on the angle \( \theta_0 \) if the machine is saturated. Under the assumptions \( L_{\mu 0} = L_{\mu 0} \) and \( L_{\tau 0} = 0 \), the impedance (31) can be written as

\[
Z_s(s) = e^{\theta_0 J} \left[ R_\sigma + sL_\sigma - \omega_m L_\sigma + sL_{\tau 0} \right] e^{-\theta_0 J}
\]

According to the approximate reduced-order model (35), the saturation of the rotor leakage inductance provides information of the direction of the operating-point rotor current vector \( \tilde{i}_0 \) (or the vector \( -J\tilde{\psi}_0 \) since \( \tilde{u}_0 = [0, 0]^T \) is assumed). These saturation-induced saliencies related to the direction of \( \tilde{\psi}_0 \) may be exploited in flux-angle estimation, e.g. [5], [6]. Furthermore, these saliencies should be taken into account when adapting \( L_\sigma \) and \( R_\sigma \) using signal-injection methods similar to [17]. However, since the assumption \( L_{\tau 0} = 0 \) does not usually hold for machines with skewed or closed rotor slots, the approximate reduced-order model (35) should be used with care.

VI. RESULTS

Small-signal characteristics of a 2.2-kW squirrel-cage induction machine were studied by means of two-dimensional time-stepping FEA [13] and laboratory experiments. The machine is equipped with closed and skewed rotor slots, and its rating is: voltage 400 V; current 5 A; frequency 50 Hz; speed 1436 r/min; and torque 14.6 Nm. The base values are: angular frequency 2π50 rad/s; voltage \( \sqrt{2}/\sqrt{3} \times 400 \) V; and current \( \sqrt{2}/5 \) A.

A. Finite-Element Analysis at Rated Operating Point

Three different kinds of tests were carried out using time-stepping FEA: the voltage-pulse test; the pulsating voltage-signal injection test; and the speed-pulse test. Parameters of the proposed model were identified based on the data from the voltage-pulse test, and the predictions of the model are compared with the results from the other two independent tests. The rated operating point is considered. The skewing of the rotor slots is not modeled in FEA.

1) Voltage-Pulse Test: Several frequencies can be simultaneously excited by means of a pulse test. Hence, the number of time-stepping FEA simulations required for gathering frequency-response data can be significantly reduced as compared to harmonic excitation. Here, the voltage pulse is defined by [14]

\[
\tilde{u}_s = \begin{cases} u_b \sin^2(\omega_s t), & 0 \leq t \leq 1/(2\omega_b) \\ 0, & \text{otherwise} \end{cases}
\]

where \( u_b = 0.1 \) p.u. and \( \omega_b = 4 \) p.u. The duration time \( 1/(2\omega_b) \) corresponds to 2.5 ms. The pulse test was performed twice with perpendicular pulses, whose directions are illustrated in Figs. 3(a) and 3(b). The pulse was first applied to the \( d \) direction, i.e. \( \tilde{u}_s = [\tilde{u}_d, 0]^T \), and then to the \( q \) direction, i.e. \( \tilde{u}_s = [0, \tilde{u}_q]^T \); the \( d \) axis is aligned with the operating-point stator voltage.
frequencies (below 0.2 p.u.) are used. At higher frequencies, was investigated. The model fits well if only the lowest saturation effect decreases the goodness of the fit significantly the saturation of the rotor leakage inductance and the mutual inductance operating point.

are physically reasonable, and they are consistent with the results of time-stepping computations were transformed to the frequency domain using DFT. Since two pulse tests were made, it was possible to calculate all four small-signal admittances $Y_{dd}(j\omega)$, $Y_{dq}(j\omega)$, $Y_{qd}(j\omega)$, and $Y_{qq}(j\omega)$.

The admittance matrix (26) of the proposed model was fitted to the frequency response data obtained from time-stepping FEA. The inductances $L_{s0}$, $L_{r0}$, $L_{m0}$, $L_{r0}$, and $L_{t0}$ and the stator resistance $R_s$ were allowed to vary freely in the data fitting. These parameters together with the operating-point data ($\tilde{u}_{d0}$, $\tilde{u}_{s0}$, $\omega_{d0}$, and $\omega_{s0}$) obtained from FEA were used to calculate the operating-point rotor current from (22). $R_s$ from (23), and $L_{t0} = L_{r0} - L_{m0}$ from (24). An estimate of the admittance matrix was calculated according to (26). The cost function used in the data fitting is the sum of the square errors of the elements in the admittance matrix. The result of the data fitting is presented in Fig. 4 by solid lines. As can be seen, the model fits rather well to the data. At frequencies close to 3 p.u., the influence of the skin effect begins to decrease the goodness of the fit. If needed, the skin effect could be taken into account by an additional rotor branch [18]. The circles and crosses in Fig. 4 show the admittances from the FEA data in the operating-point stator-voltage coordinates. If the motor were not saturated, the circles and crosses would overlap.

Table I gives the parameters obtained by fitting the proposed model using the FEA data shown in Fig. 4. The fitted parameters are physically reasonable, and they are consistent with the operating point.

For comparison, the model (26) with the assumptions $L_{t0} = L_{r0}$ and $L_{t0} = 0$, corresponding to the model in [10], was investigated. The model fits well if only the lowest frequencies (below 0.2 p.u.) are used. At higher frequencies, the saturation of the rotor leakage inductance and the mutual saturation effect decrease the goodness of the fit significantly (or nonphysical parameter values are obtained as a result).

In some applications, the stator impedance matrix may be preferred over the stator admittance matrix. Solid lines in Fig. 5 show the stator impedances corresponding to the fitted admittances in Fig. 4. The d axis is aligned with the operating-point stator voltage. The dashed lines present the impedances calculated using the reduced-order model (31). The curves differ significantly at low frequencies but they practically overlap at frequencies above 1 p.u.

2) Pulsating Voltage-Signal Injection Test: The pulsating excitation voltage was applied in time-stepping FEA in the direction of the d axis of a synchronously rotating coordinate system, i.e. $\tilde{u}_d = [u_c \sin(\omega t), 0]^T$. The amplitude $u_c = 0.025$ p.u. and the angular frequency $\omega = 1.2$ p.u. were used. The resulting small-signal current responses $i_{sd}$ and $i_{sq}$ were transformed to the frequency domain, and the small-signal stator admittances $Y_{dd}(j\omega)$ and $Y_{qd}(j\omega)$ were calculated.
evaluate the effect of the direction of the excitation signal on the admittances, the direction of the excitation signal (i.e., the orientation of the \( d \) axis) was varied with respect to the operating-point stator voltage as illustrated in Fig. 3(c); the angle \( \vartheta_0 \) was varied in steps of \( 10^\circ \). The \( d \) axis is aligned with the operating-point stator voltage at \( \vartheta_0 = 0 \).

The admittances obtained using the pulsating voltage-signal injection tests are depicted in Fig. 6. It can be seen that the admittances depend significantly on the angle \( \vartheta_0 \). For comparison, the admittances corresponding to the proposed model are shown by the solid lines in the figure. These admittances were calculated using (26) with the parameters in Table I and the coordinate transformation (27). It can be seen that the proposed model fits very well to the data from the signal-injection test. It is worth noticing that \( Y_{qq}(\vartheta_0) = Y_{dd}(\vartheta_0 - \pi/2) \) and \( Y_{dq}(\vartheta_0) = -Y_{qd}(\vartheta_0 - \pi/2) \).

3) Speed-Pulse Test: The transfer function from the rotor speed to the electromagnetic torque was investigated by applying an pulse to the speed while the motor was supplied by a sinusoidal voltage in time-stepping FEA [19]. Transforming this data into the frequency domain, the frequency response shown by the circles in Fig. 7 is obtained. For comparison, the frequency response was calculated using (30) and the parameter values given in Table I. This transfer function is shown in Fig. 7 by the solid line. It can be observed that the proposed model fits well to the data from the speed pulse test. Hence, the fitted parameter values—obtained from the voltage-pulse tests—are consistent with the data from the speed-pulse test.

B. Experiments Under Locked-Rotor Condition

In the laboratory experiments, a 2.2-kW induction machine was fed by a frequency converter controlled by a dSPACE DS1103 PPC/DSP board. The rotor was mechanically locked; this operating condition was chosen to ensure that there is no oscillation in the rotor speed, i.e., \( \dot{\omega}_m = 0 \) holds. The stator

Fig. 8. Admittances from measurements (circles and crosses) and from fitted model (26) (solid lines) in coordinates fixed to $u_s^0$: (a) $Y_{dd}(j\omega)$ shown by thick line and circles, $Y_{qq}(j\omega)$ shown by thin line and crosses; (b) $Y_{qd}(j\omega)$ shown by thick line and circles, $Y_{dq}(j\omega)$ shown by thin line and crosses. In the case of no saturation, conditions $Y_{dd}(j\omega) = Y_{qq}(j\omega)$ and $Y_{qd}(j\omega) = -Y_{dq}(j\omega)$ would hold.

The admittance matrix (26) of the proposed model was fitted to the measured frequency response data as described in Section VI-A1. The result of the data fitting is presented in Fig. 8 by the solid lines, and the corresponding parameters are given in Table II. It can be seen that the proposed model fits well and the fitted parameters are physically reasonable. The small differences between the measured and fitted admittances may originate from measurement errors and from phenomena omitted in the model (e.g., skin effect and iron losses).

The effect of the direction of the excitation signal on the small-signal admittance was also analyzed. The voltage signal pulsating at the frequency $\omega = 1.2$ p.u. was used; the angle $\theta_0$ was varied in steps of $10^\circ$ with respect to the operating-point stator voltage, cf. Fig. 3(c). The measured admittances are shown by the circles in Fig. 9. The admittances corresponding to the proposed model are shown by the thick lines in the figure. These admittances were calculated using (26) with the parameters in Table II and the coordinate transformation (27). It can be seen that the proposed model can predict the admittance as a function of the direction of the excitation signal. It is to be noted that the temperature and the resistances increased while performing the test at different angles. In Fig. 9, the measured admittances at $\theta_0 = 180^\circ$ differ from those at $\theta_0 = 0^\circ$ mainly due to the temperature rise.

For comparison, the model (26) with the assumptions $L_{r^0\sigma^0} = L_{r\sigma^0}$ and $L_{r^0} = 0$, corresponding to the model in [10], was fitted to the measured data shown in Fig. 8. The fitted parameters are given in Table II. The model fits well only at the lowest excitation frequencies. As an example, the admittance at the excitation frequency $\omega = 1.2$ p.u. as a function of the excitation-signal angle $\theta_0$ is depicted by the thin lines in Fig. 9. It can be observed that the prediction from the proposed model is superior to that from the model in [10].

VII. CONCLUSIONS

The magnetic saturation can be taken into account when deriving a small-signal model for the induction machine. The proposed model takes into account the mutual saturation effect originating mainly from skewed and closed rotor slots, and it fulfills the reciprocity conditions. The model can be applied to parameter identification and to the analysis and development of flux angle estimation methods. Furthermore, the small-signal relationship between the rotor speed and the electromagnetic torque—needed if torsional dynamics are
yielding the state-space representation \( \dot{\tilde{z}} = T^{-1}B_r \),\( g = T^{-1}b \), and \( F = T^{-1}AT \) \[ \begin{bmatrix} F_{11} & F_{12} \\ F_{21} & F_{22} \end{bmatrix} \] (40)

\[ G_s = T^{-1}B_s = \begin{bmatrix} G_{s1} \\ G_{s2} \end{bmatrix} \] (41)

Since \( \dot{\omega}_m \) does not affect the stator impedance, \( \dot{\omega}_m = 0 \) will be assumed for simplicity in the following. Furthermore, a short-circuited rotor winding is considered, i.e. \( u_r = [0, 0]^T \). The stator-current dynamics are usually significantly faster than the rotor-flux dynamics. Hence, \( \psi_r = [0, 0]^T \) can be assumed at higher frequencies, and the state-space representation (39) reduces to

\[ L_s \frac{d\tilde{i}_s}{dt} = u_s - R_s \tilde{i}_s - \omega_m J L_s \tilde{i}_s \] (42)

where the total leakage inductance matrix is \( L_s = G^{-1} \) and the total resistance matrix is \( R_s = -L_s T_{11} - \omega_m J L_s \). After Laplace transforming (42), the reduced-order stator-impedance matrix (31) is obtained.
