(Received 28 May 2014; accepted 11 August 2014; published 25 August 2014)

The fracture strength of Al_2O_3 membranes deposited by atomic layer deposition at 110, 150, 200, and 300 °C was investigated. The fracture strength was found to be in the range of 2.25–3.00 GPa using Weibull statistics and nearly constant as a function of deposition temperature. This strength is superior to common microelectromechanical systems materials such as diamondlike carbon, SiO_2 , or SiC . As-deposited membranes sustained high cycling pressure loads >10 bar/s without fracture. Films featured, however, significant reduction in the resistance to failure after annealing (800 °C) or high humidity (95%, 60 °C) treatments. © 2014 American Vacuum Society.

I. INTRODUCTION

Thin films produced by atomic layer deposition (ALD) have attracted great attention. Due to their excellent properties, ALD films have very good conformality and uniformity, and they can be deposited on various three dimensional substrates. ALD films have been applied in biomedical, optical, electronic devices, etc.¹ ALD films are widely used in micro- and nanoelectromechanical systems (MEMS/NEMS): for instance, as antistiction, wear resistant, or other functional layers.^{2–10} MEMS/NEMS consist of moving parts with mechanical functions, where fracture strength (resistance to failure) and durability are important parameters. Moreover, moisture and temperatures can influence to the fracture strength, and therefore, this influence must be analyzed and understood prior to device fabrication. Failure characterization of nanometer-thick films is challenging: besides complex sample preparation steps, analysis may require an additional modeling. Bulge technique is a straightforward and simple mechanical test, which produces fracture strength values for thin films.^{11–15} Fracture toughness testing is more demanding and requires patterning of initial crack with nanometer size and shape control (by, e.g., focused ion beam).¹⁵

In this paper, the fracture bulge technique with free-standing ALD Al_2O_3 membranes deposited at 110, 150, 200,

and 300 °C (70–75 nm thick) was conducted. ALD Al_2O_3 films with excellent mechanical stability and high robustness are demonstrated. In addition to the experiments on effect of humidity and annealing on strength, we carried out high speed pressure cycling tests on membranes. These conditions were selected as ones which could be during MEMS/NEMS sensors operations, for example, in space or automotive applications.^{16,17} These sensors should reliably operate during outgassing of moisture or temperature drifts without device disruption.¹⁸ Another example of MEMS is microheaters and microhotplates, which operate at significantly high temperatures (up to 1000 °C).^{19,20} It is therefore important to evaluate the change in fracture strength of thin films after heating or moisture treatments.

II. EXPERIMENT

ALD Al_2O_3 films were deposited in a top-flow PicosunTM R-150 ALD reactor. Precursors were trimethylaluminum (electronic grade Me_3Al , SAFC Hitech) and deionized water. Me_3Al precursor was cooled with a Peltier element to about 17 °C and water was used at a room temperature without cooling.²¹ Nitrogen (purity > 99.999%) was used both as a purge gas and for flushing the reactant lines with a constant 200 sccm flow. Precursor dose and purge times were 0.1 and 4.0 s, respectively, for films deposited at 110 °C to 200 °C and 0.1 and 1.0 s for film deposited at 300 °C. The number of ALD cycles was 962, 853, 778, and 756 for 110, 150,

^{a)}Electronic mail: maria.berdova@aalto.fi

200, and 300 °C, respectively. Film thicknesses were measured with SCI FilmTek 2000 M spectroscopic reflectometer using 25-point automated measurement. Dispersion of the refractive index for the Al₂O₃ deposited at 300 °C (5000 cycles) was used as a standard model for the measurement recipe. The targeted film thickness was 75 nm, and the measured film thickness was in the range of 73 ± 2 nm.

After the deposition of the ALD films on double side polished silicon substrate [Fig. 1(a)], the back side was patterned employing laser lithography (Microtech LW405) and wet etching of Al₂O₃ in buffered hydrofluoric acid (BHF) for 1 min at 31 °C [Fig. 1(b)], while the top side Al₂O₃ was protected by standard photoresist to avoid etching of test structures. The patterned Al₂O₃ from the back side acted as an etch mask for deep reactive ion etching (DRIE) since the etch selectivity of silicon to Al₂O₃ is 66 000:1,²² and Al₂O₃ from the top side acted as an etch stop layer. Finally, membranes (400 μm in radius) were released by DRIE Bosch process [Fig. 1(b)] utilizing SF₆, O₂ and C₄F₈ gases (STS Advanced Silicon Etch). Additionally, each chip (7 mm²) with a test structure was defined by patterning line borders to avoid dicing [Fig. 1(c)]. The fabrication of free-standing membranes was reported in detail elsewhere.¹⁴

After sample fabrication, some membranes underwent annealing (PEO-601) at 800 °C for 15 min in nitrogen ambient, while others were kept in an environmental chamber with constant relative humidity (RH) of 95% at 60 °C for 18 h (around 15 samples per each deposition temperature for every treatment).

Due to the fact that crystalline Al₂O₃ has different elastic properties from amorphous films,²³ and crystallization can start at annealing temperatures about 750–800 °C,²⁴ annealed Al₂O₃ films were analyzed for crystallinity using grazing-incidence x-ray diffraction (GIXRD) method.

In the bulge testing, thin film breakage was brought about by applying overpressure to membrane from the top side [Fig. 1(d)]. The differential pressure (compressed air) was gradually increased by 100 mbar/s until membrane rupture. Maximum available differential pressure was 3500 mbar. The breakage pressure was recorded by measurement

software. In addition, as-deposited membranes were subjected for high speed pressure cycling testing: ten cycles with the maximum available ramp rate of >>10 bar/s were applied until 1500 mbar. Next ten cycles with the same ramp rate were applied to the same membrane until 2000 mbar.

The fracture strength σ_{fracture} of a membrane was evaluated from maximum pressure P_{max} using equation^{12–14}

$$\sigma_{\text{fracture}}^3 = \frac{1}{24} \frac{EP_{\text{max}}^2 a^2}{(1-\nu)h^2}, \quad (1)$$

where a is the membrane radius, h is the film thickness, E is the Young's modulus, and ν is the Poisson's ratio [assumed to be 0.24 (Ref. 25) here] of Al₂O₃ film.

The probability of failure P_f was estimated by the probabilistic Weibull distribution,^{26–30} where the failure probability for a specimen with a surface area A under uniformly applied stress σ is described by function

$$P_f = 1 - \exp \left[-A \left(\frac{\sigma}{\sigma_c} \right)^m \right], \quad (2)$$

where σ_c is the characteristic failure strength (scale parameter) value of a unit area of material at 63% or $(1 - e^{-1}) \cdot 100\%$, m is the Weibull modulus (shape parameter), which evaluates the scatter of the strength data and measures engineering reliability.

The expected mean fracture strength was calculated from^{30,31}

$$\bar{\sigma} = \frac{\sigma_c}{A^{1/m}} \cdot \Gamma \left(1 + \frac{1}{m} \right), \quad (3)$$

and the standard deviation from

$$s = \sqrt{\bar{\sigma}^2 \cdot \left(\frac{\Gamma \left(1 + \frac{2}{m} \right)}{\Gamma^2 \left(1 + \frac{1}{m} \right)} \right)}, \quad (4)$$

where $\Gamma(z)$ is the gamma function.

(Color online) Fabrication process of free-standing membranes and schematic image of the fracture bulge test principle: (a) atomic layer deposition of Al₂O₃ from both sides; (b) wet etching of Al₂O₃ in BHF from the back side, membrane release using dry etching; (c) photo image of test structures; (d) overpressure P (compressed air) is applied from the membrane top, where a is the radius, h is thickness of membrane.

FIG. 2. Average breakage pressure values vs deposition temperatures.

III. RESULTS AND DISCUSSION

The bulge technique was used to evaluate the fracture strength of ALD Al_2O_3 deposited at four different temperatures. Overpressure with maximum value of 3500 mbar was applied to the suspended membrane until fracture took place. The measured breakage pressure values are shown in Fig. 2. As can be seen, films deposited at 150 °C and 300 °C tolerated higher pressures than those deposited at 110 °C or 200 °C. All membranes survived after high speed pressure cycling without any failure. This is a considerable merit since membranes could withstand shock pressure impacts with a high robustness needed for various MEMS devices. However, after annealing or high humidity treatments, membranes became significantly weaker (with exception of the sample deposited at 110 °C).

The fracture strength was determined by Eq. (1). GIXRD revealed no significant peaks indicating amorphous nature of all annealed Al_2O_3 films. Therefore, Young's moduli were assumed to be 150 GPa for deposition at 110 °C, and 170 GPa for all other deposition temperatures.²¹

Table I represents shape and scale parameters derived from failure probability-fracture strength fits (Fig. 3) using probabilistic Weibull distribution [Eq. (2)]. The Weibull modulus of each test structure was defined from the slope of the fit, and the characteristic strength was estimated with probability of 63%. As most good engineering ceramics,

TABLE I. Scale (σ_c) and shape (m) parameters for all test structures.

Deposition T (°C)	As-deposited scale (GPa) ^m	After annealing ^a scale (GPa) ^m	After humidity scale (GPa) ^m
110	2.32 ^{16.8}	2.41 ^{19.2}	1.62 ^{13.6}
150	3.07 ^{9.0}	2.36 ^{14.0}	2.15 ^{11.1}
200	2.62 ^{9.8}	1.30 ^{14.7}	1.51 ^{8.5}
300	3.10 ^{15.4}	2.16 ^{11.7}	2.10 ^{14.7}

^a25–30% of test structures failed after annealing without any mechanical load.

FIG. 3. (Color online) Weibull diagrams: failure probability vs fracture strength, where characteristic failure strength is scale and Weibull modulus is shape parameter. Shown for Al_2O_3 deposited at 300 °C.

Al_2O_3 had the shape parameter about ten and higher. Aluminum oxide films deposited at 150 °C and 300 °C had the highest values of the scale parameter. However, the scale parameter of these films was reduced by ~30% after annealing or moisture treatments. Interestingly, thin films deposited at 200 °C reduced their scale parameter almost by a factor of two after high humidity or annealing.

Figure 4 shows the dependence of the mean fracture strength values [Eq. (3)] versus deposition temperature for all sample types: as-deposited, annealed, and treated in high humidity chamber. As observed, the fracture strength degraded significantly after being annealed or exposed to the high humidity. Error sources include minor membrane thickness variation due to ALD, the Bosch etch process undercut affects membrane size and thickness to some extent.

The fracture strength of as-deposited films is well-correlated with the earlier work where the strength Al_2O_3

FIG. 4. Mean fracture strength values [Eq. (3)] vs deposition temperatures.

films was of 2.56 ± 0.21 GPa (deposited at 220°C).¹⁴ As-deposited Al_2O_3 exhibits significantly high fracture strength values in comparison with common MEMS materials such as silicon oxide, diamondlike carbon (DLC) or silicon carbide: 0.6–1.9 GPa (Ref. 32) for silicon oxide, 0.7 GPa (Ref. 33) for DLC, and 0.81 GPa (Ref. 34) for silicon carbide. The fracture strength of aluminum oxide is comparable with polysilicon films, whose strength is about 3 GPa (Ref. 34) and slightly lower than ultrananocrystalline diamond or silicon nitride deposited by low pressure chemical vapor deposition: fracture strengths are 3.95–5.03 GPa (Ref. 33) and 5.69 GPa (Ref. 11), respectively.

High humidity reduced the Al_2O_3 membrane fracture strength. ALD aluminum oxide has been studied extensively as a water vapor barrier, and its tendency to degrade is well documented.^{35–37} One of very few reports on mechanical properties of alumina films is from 1969,³⁸ when it was reported that Young's modulus of Al_2O_3 films is reduced as a function of absolute humidity. It has also been shown that it is difficult to measure inherent strength of alumina because even low humidity in the range of 10–40% RH is affecting the results.³⁹ They proposed sample coating and nitrogen enclosure for the measurements. Others have shown that even very thin coatings, a few nanometer TiO_2 or NiO , can remarkably stabilize alumina under water immersion.⁴⁰ ALD Al_2O_3 is etched by deionized water with the etch rate of 0.2 nm/min.⁴¹ Water is able to penetrate the lattice of the Al_2O_3 film, and possibly react with hydroxyl groups, creating paths for moisture penetration.³⁹ Thus, corrosion and dissolution of the film in water could be the reasons for the strength reduction.

In case of annealing (except for sample deposited at 110°C), the decrease in resistance to failure can be explained by modification in composition (outgassing) after annealing.^{42,43} It has been reported that hydrogen and oxygen contents are reduced during annealing.^{42,43} Moreover, annealing induces changes in stress level that can lead to failure. Indeed, some of our membranes failed after annealing without any mechanical load (25–30% of samples).

The fracture strength of bulk Al_2O_3 is known to decrease with increasing temperature and relative humidity.^{39,44} The same tendency was observed in our results: high humidity and annealing had a deleterious effect to the strength of ALD Al_2O_3 , degrading the membrane pressure tolerance and therefore weakening the material strength.

IV. CONCLUSIONS

Reliable MEMS performance significantly depends on materials used for its fabrication. ALD Al_2O_3 can be considered as a successful candidate for fabricating reliable free-standing structures. As-deposited ALD Al_2O_3 membranes exhibited high mechanical robustness and considerable fracture strength of 2.25–3.00 GPa. Aluminum oxide films deposited at 150°C and 300°C tolerated higher pressures; however, the mean fracture strength remained nearly constant as a function of deposition temperature. Furthermore, as-deposited membranes sustained high speed pressure

cycling without breakage. High humidity and annealing at high temperatures were found to reduce fracture strength clearly. Future work is required to evaluate the size effect of ALD thin films and to elucidate the mechanism of humidity induced failure.
