ABSTRACT

We present first results on polarization swings in optical emission of blazars obtained by RoboPol, a monitoring programme of an unbiased sample of gamma-ray bright blazars specially designed for effective detection of such events. A possible connection of polarization swing events with periods of high activity in gamma-rays is investigated using the data set obtained during the first season of operation. It was found that the brightest gamma-ray flares tend to be located closer in time to rotation events, which may be an indication of two separate mechanisms responsible for the rotations. Blazars with detected rotations during non-rotating periods have significantly larger amplitude and faster variations of polarization angle than blazars without rotations. Our simulations show that the full set of observed rotations is not a likely outcome (probability $\leq 1.5 \times 10^{-2}$) of a random walk of the polarization vector simulated by a multicell model. Furthermore, it is highly unlikely ($\sim 5 \times 10^{-5}$) that none of our rotations is physically connected with an increase in gamma-ray activity.

Key words: polarization – galaxies: active – galaxies: jets – galaxies: nuclei.

1 INTRODUCTION

Blazars are active galactic nuclei whose jets are oriented close to our line of sight, so that we observe high relativistic beaming of their non-thermal emission and large amplitude variability at all wavelengths. The low-frequency emission is dominated by synchrotron radiation, and hence is highly polarized. The exact polarization fraction and direction depend on the structure of the magnetic field in the emitting region, and on the number of emitting regions along the line of sight. The polarization direction (in the simple case of a single dominant emission region) traces (and is perpendicular to) the direction of the projected magnetic field on the plane of the sky. Already from early optical observations, it has been known that polarization parameters of blazars are variable on daily time-scales (Kinman, Lamla & Wirtanen 1966). In general, both flux density and polarization exhibit an erratic variability (Angel & Stockman 1980; Uemura et al. 2010; Ikejiri et al. 2011), which could be interpreted as a random walk (Moore et al. 1982). However, in some cases the electric vector position angle (EVPA) of the polarized emission displays long, smooth and monotonic rotations which have been observed in the optical since the 1980s (Kikuchi et al. 1988). A number of mechanisms have been proposed for the interpretation of such events, including: stochastic variations of turbulent magnetic fields, a shock travelling in a non-axisymmetric jet (Konigl & Choudhuri 1985), polarized flares in the accretion disc (Sillanpää et al. 1993), two-component models consisting of two independent sources of polarized emission (Bjornsson 1982), and jet bending (Abdo et al. 2010a).

Blazars represent the most common class of known gamma-ray sources (Nolan et al. 2012; The Fermi-LAT Collaboration 2015). Despite the recent progress in the field, many questions concerning
the high-energy emission produced by blazars are still under debate. For instance, it is unclear where the gamma-ray emitting site is located: within the broad-line region (e.g. Blandford & Levinson 1995; Poutanen & Stern 2010) or well downstream in the jet (e.g. Marscher et al. 2008; Agudo et al. 2011).

Recent work showed that at least some large EVPA swings can be associated with gamma-ray flares (e.g. Abdo et al. 2010a; LaRionov et al. 2013b) and therefore can possibly provide some insight on the physics of high-energy activity. Although such events have triggered an increasing interest in polarimetric monitoring of gamma-ray blazars, efforts in this direction have been based on selected cases comprising statistically biased samples. As a result, a significant amount of invaluable polarimetric data sets for a large number of sources has been gathered. However, this set cannot be used for statistically rigorous population studies and, in particular, the investigation of a possible correlation between gamma-ray flares and optical EVPA rotations. The RoboPol programme (King et al. 2014; Pavlidou et al. 2014) has been designed to provide a data set of rotation events in an unbiased sample of blazars, appropriate for such studies.

In this paper, we analyse EVPA rotations detected by RoboPol during the first observing season between 2013 July and November. After a brief description of observing and reduction techniques in Section 2, we estimate the frequency of EVPA rotations in blazars and list their properties in Section 3. A Monte Carlo (MC) simulation is performed in Section 4 in order to determine whether the EVPA rotations can be produced by random walk processes. In Section 5 we study the possible connection between an increased activity in the gamma-ray band and EVPA swings. Our findings are summarized in Section 6.

## 2 OBSERVATIONS AND DATA REDUCTION

### 2.1 Our sample

A unique feature of the RoboPol programme is that it is monitoring a sample which has been selected on the basis of strict, bias-free and objective criteria (for detailed discussion on the sample construction, see Pavlidou et al. 2014). The sample consists of three distinct groups.

(i) The main (‘gamma-ray–loud’) sample is an unbiased subset of a statistically complete flux-limited sample of blazars from the second Fermi-LAT source catalogue (Nolan et al. 2012). Specifically, we selected all the sources in the second Fermi-LAT (2FGL) catalogue classified as BL Lacertae objects (bzb), Flat Spectrum Radio Quasars (bsq), or active galaxy of uncertain type (agu). Applying the selection criteria listed in Table 1, we constructed a gamma-ray flux-limited ‘parent sample’. Application of the visibility constraints and field-quality cuts resulted in an unbiased subsample of 83 sources, among which we randomly selected 62 sources.

(ii) A ‘control’ sample of 15 ‘gamma-ray–quiet’ sources. It constitutes an unbiased subset of a statistically complete sample of blazars. It has been drawn from the CGRaBS catalogue (Healey et al. 2008) by applying the selection criteria listed in Table 1.

(iii) 24 additional sources chosen on the basis of their variability characteristics or their presence either in the F-Gamma (Fermi-GST AGN Multi-frequency Monitoring Alliance) programme sample or in TeV catalogues.

Although here we present the polarization swings detected in all monitored sources during the first RoboPol observing season, the statistical analysis in this paper is based only on sources from the group (i).

### 2.2 Optical observations

All photometric and polarimetric measurements were done at the 1.3-m telescope of Skinakas observatory using RoboPol, a polarimeter specifically built for the project (King et al. 2014). The RoboPol instrument contains a fixed set of two Wollaston prisms and half-wave plates, which splits each incident ray into four rays with polarization plane rotated 45° with respect to each other. Measuring relative intensities in pairs of the rays for each object in the 13 arcmin × 13 arcmin field, we obtain the fractional Stokes parameters

\[
\begin{align*}
q &= (I_3 - I_2)/(I_1 + I_2) = Q/I \\
\chi &= (I_3 - I_2)/(I_1 + I_2) = U/I
\end{align*}
\]

Stokes parameter \( I \) is calculated as a sum of intensities of all four elements.

The data presented in this paper were taken with the \( R \)-band filter. Magnitudes were calculated using calibrated field stars either found in the literature or presented in PTF (Palomar Transient Factory) \( R \)-band catalogue (Ofek et al. 2012) or USNO-B1.0 catalogue (Monet et al. 2003), depending on availability.

The exposure length was adjusted by the brightness of each target, which was estimated during the short pointing exposures.

Notes. 1\(^{\text{Refers to elevation during Skinakas dark hours.}}\)

\(^{2}\text{Average value between archival value and measured during preliminary RoboPol observations (when applicable).}\)
depending also on the sky conditions. The average photometric error in magnitudes is 0.04 mag. The data were processed using the specialized pipeline described in detail by King et al. (2014) along with the telescope control system.

Since we have introduced a Galactic latitude cut selecting objects with $|b| > 10^\circ$, the average colour excess in the directions of our targets is relatively low, $E(B-V) = 0.11^m$ (Schlafly & Finkbeiner 2011), implying that the interstellar polarization is less than 1.0 per cent on average (Serkowski, Mathewson & Ford 1975).

The statistical uncertainty in the degree of polarization is less than 1 per cent in most cases, while the EVPA is typically determined with a precision of $1^\circ$–$10^\circ$ depending on the source brightness and fractional polarization. Detailed description of the instrument model and error analysis is given in King et al. (2014).

In order to resolve the $180^\circ$ ambiguity of the EVPA we followed a standard procedure (see e.g. Abdo et al. 2010a; Ikejiri et al. 2011; Kiehlmann et al. 2013), which is based on the assumption that temporal variations of the EVPA are smooth and gradual, hence adopting minimal changes of the EVPA between consecutive measurements. We define the EVPA variation as

$$\Delta \theta_n = |\theta_{n+1} - \theta_n| - \sqrt{\sigma(\theta_{n+1})^2 + \sigma(\theta_n)^2},$$

where $\theta_{n+1}$ and $\theta_n$ are the $n+1$ and $n$th points of the EVPA curve and $\sigma(\theta_{n+1})$ and $\sigma(\theta_n)$ are the corresponding errors of the position angles. If $\Delta \theta_n > 90^\circ$, we shift the angle $\theta_{n+1}$ by $\pm n \times 180^\circ$, where the integer $\pm n$ is chosen in such a way that it minimizes $\Delta \theta_n$. If $\Delta \theta_n \leq 90^\circ$, we leave $\theta_{n+1}$ unchanged.

Our first period of regular photometric and polarimetric monitoring of blazars started in 2013 July and lasted until the end of 2013 November. During the five-month period we obtained more than 1100 measurements of 101 objects from our sample almost uniformly spread over the observing season of each object. The median cadence and total season length for objects with $\Delta t$-median smaller than 20 d (including the June survey data; Pavlidou et al. 2014) is presented in Fig. 1, which is discussed in more detail in Section 3.3.

2.3 Gamma-ray observations

The gamma-ray data were obtained with the Large Area Telescope (LAT) onboard the Fermi gamma-ray space observatory, which observes the entire sky every 3 h at energies of 20 MeV – 300 GeV (Atwood et al. 2009). We analysed LAT data in the energy range $100 \text{ MeV} \leq E \leq 100 \text{ GeV}$ using the unbinned likelihood analysis of the standard Fermi analysis software package Science Tools v9r33p0 and the instrument response function $P_{\text{REP SOURCE}}^V$. Source class photons (evclass=2) were selected within a $15^\circ$ region of interest centred on a blazar. Cuts on the satellite zenith angle ($<100^\circ$) and rocking angle ($<52^\circ$) were used to exclude the Earth limb background. The diffuse emission from the Galaxy was modelled using the spatial model $gll_{\text{psf}}$ (Schlafly & Finkbeiner 2011), implying that the interstellar polarization is less than 1.0 per cent on average (Serkowski, Mathewson & Ford 1975).

The statistical uncertainty in the degree of polarization is less than 1 per cent in most cases, while the EVPA is typically determined with a precision of $1^\circ$–$10^\circ$ depending on the source brightness and fractional polarization. Detailed description of the instrument model and error analysis is given in King et al. (2014).

3 RESULTS

3.1 Detected rotations of EVPA

The optical emission polarization plane of blazars is often variable even within the course of a single night. There is no objective physical definition of an EVPA rotation. Strictly speaking, any change of the EVPA between two measurements constitutes a rotation. However, typically only high-amplitude ($>90^\circ$), smooth and well tracked variations of the EVPA are considered as rotations in the literature.

We accept a swing between two consecutive EVPA measurements $\Delta \theta = |\theta_{i+1} - \theta_i|$ as significant if $\Delta \theta > \sqrt{\sigma(\theta_{i+1})^2 + \sigma(\theta_i)^2}$.

We define as an EVPA rotation any continuous change of the EVPA curve with a total amplitude $\Delta \theta_{\text{max}} > 90^\circ$, which is comprised by at least four measurements with significant swings between them. Start and end points of a rotation event are defined by a change of the EVPA curve slope $\Delta \theta_i / \Delta t_i$ by a factor of 5 or a change of its sign. This definition is rather conservative, and is in general consistent with rotations reported in the literature.

Using this definition, we identified 14 rotations of the EVPA in 12 blazars from the main sample during the season of 2013 (see Table 2). This number is comparable to the number of previously

\[^2\]http://fermi.gsfc.nasa.gov/ssc/data/access/lat/2yr_catalog/gll_psc_v07.xml
known events of this type. Two more blazars with detected rotations, namely RBPLJ0721+7120 and RBPLJ0854+2006, belong to the additional sample of hand-picked sources. These blazars/events were not included in the statistical or frequency analysis of the following sections in this paper. The full season EVPA curves along with the evolution of the polarization degree and the R-band flux density, for all 14 blazars with detected rotations, are shown in Fig. 2 and listed in Table 2. The EVPA rotations are marked by density, for all 14 blazars with detected rotations, are shown in Fig. 2.

Table 2. Observational data for EVPA rotations detected by RoboPol in 2013. 3.2 General properties of EVPA rotations and rotators

We estimated the maximal amplitude $\Delta \theta_{\text{max}}$ and the duration of the rotations $T_{\text{rot}}$, using the first and last points of each event. Due to a moderate sampling and 180° EVPA ambiguity, the rotation start and/or end points cannot be pinpointed accurately in five cases (namely RBPLJ0136+4761, RBPLJ0259+0747, RBPLJ1048+7143, RBPLJ1806+6949 and RBPLJ2311+3425). This ambiguity affects the estimated $\Delta \theta_{\text{max}}$ and $T_{\text{rot}}$ of the event, which should really be considered as lower limits in this case. We also estimated the average rotation rate as $\langle \Delta \theta / \Delta t \rangle = \Delta \theta_{\text{max}}/T_{\text{rot}}$ of these parameters as well as the blazar class and the TeV emission flag are listed in Table 2.

We also collected data from the literature on previously known rotations of EVPA in blazars which show this behaviour (‘rotators’ hereafter). Rates and $\Delta \theta_{\text{max}}$ of these rotations were estimated from plots in the respective papers. These parameters as well as the blazar class and the TeV emission flag are listed in Table 2.

The distribution of $\Delta \theta_{\text{max}}$ and rates of EVPA rotations from historical and RoboPol data are shown in Fig. 3. The number of detected rotations clearly decreases with growing $\Delta \theta_{\text{max}}$. At the same time slow rotations dominate in the sample. This is presumably caused by a selection effect, because fast rotations require better sampling of observations.

Summarizing data on all known EVPA rotations in blazars to date we can list the following properties:

(i) all known blazars with detected EVPA rotations are in the 2FGL catalogue (i.e. they are ‘gamma-ray–loud’ sources); (ii) there are blazars known as TeV emitters as well as non-TeV sources among rotators; (iii) all subclasses of blazars show rotations of the EVPA, regardless of the position of the synchrotron peak maximum or the BL Lac/FSRQ dichotomy.
Figure 2. Evolution of polarization degree, polarization position angle and $R$-band magnitude for blazars with a detected rotation in the first RoboPol season. Periods of rotations are marked by filled black points.

Figure 3. Distributions of amplitudes and rates of EVPA rotations detected in RoboPol’s first season and reported in the literature.

(iv) there are eight blazars with more than one rotation detected. Comparison of these rotations shows that a single source can show rotations in both directions (five blazars known so far with this behaviour) and rotations observed in the same source can be of significantly different rates (in seven blazars rates differ by a factor larger than two in speed).

3.3 Observed frequency of EVPA rotations

The efficiency of an EVPA rotation detection depends on the intrinsic rate of the rotation as well as the frequency and uniformity of the observing cadence. The ambiguity of the polarization position angle introduces an upper limit on the rotation rate that can be unequivocally detected with a given typical cadence of observations.

Figure 3. (Continued).
Clearly, for a typical time interval between observations $\langle \Delta t \rangle$, no EVPA rotation with a rate higher than $90/\langle \Delta t \rangle$ can be observed.

For each blazar in our sample we found the median time difference between successive observations $\Delta t_{\text{median}}$ and the total observing season length of $T_{\text{obs}}$. These quantities (for blazars observed with $\Delta t_{\text{median}}$ ≤ 20 days) are shown in Fig. 1. In the same figure, we also plot three lines which indicate the necessary $\Delta t_{\text{median}}$ and $T_{\text{obs}}$ for detection of EVPA rotations at rates ≤ 10 (solid line), ≤ 15 (dashed line) and ≤ 20 (dotted line) degrees per day.

The leftmost vertical part of each line represents the shortest $T_{\text{obs}}$ needed to detect a rotation of $\Delta \theta_{\text{max}} = 90^\circ$ at a given rotation rate. The inclined portion of each line is determined by our requirement on a rotation event to be comprised by a minimum of four points. Given this requirement, as $\Delta t_{\text{median}}$ increases, so does $T_{\text{obs}}$. An EVPA data set with $\Delta t_{\text{median}}$ and $T_{\text{obs}}$ on that line can allow detection of EVPA rotations with $90^\circ \leq \Delta \theta_{\text{max}} \leq 270^\circ$. The horizontal part indicates the maximum $\Delta t_{\text{median}}$ allowed the detection of a rotation event under the requirement of $\Delta \theta \leq 90^\circ$ in EVPA between two consecutive points.

We can now estimate the frequency with which EVPA rotations appear in blazars as follows. Out of the 14 detected rotations in blazars of the main sample, 8 have rates less than 10 deg d$^{-1}$. There are also 41 main sample (‘gamma-ray bright’) blazars that were observed with $\Delta t_{\text{median}}$ and $T_{\text{obs}}$ (see Table 4) within the region defined by the solid line in Fig. 1. The total observing length for these blazars is 6432 d. Thereby we estimate the frequency of ‘slow’ rotations (rate < 10 deg d$^{-1}$) in the main sample sources as one rotation in ~800 d (6432 d/8 rotations). Following the same reasoning we estimate average frequencies of rotations for blazars in the main sample with rates < 15 and < 20 deg d$^{-1}$ as one rotation in ~490 d (4912/10) and ~180 d (2363/13), respectively.

### Table 4. Sources of the main and control samples within the $(\Delta \theta/\Delta t) < 10$ deg d$^{-1}$ ‘detection box’.

### 3.4 EVPA variability in blazars of different samples

In order to address the question whether ‘the EVPA variability is different in objects where rotations were detected compared to the rest of the main sample and to the control sample’ we collate all EVPA ‘swing’ events and measure their $\Delta \theta_{\text{max}}$ and rates. We define an EVPA ‘swing’ as any continuous change of the EVPA curve, without a lower limit in its $\Delta \theta_{\text{max}}$ or in the number of measurements. As before, start and end points of a swing event are defined by a change of the EVPA curve slope by a factor of 5 or a change of its sign.

We identified all such events for all blazars of the main and control samples within the 10 deg d$^{-1}$ ‘detection box’ in Fig. 1, and measured their amplitude, $\Delta \theta_{\text{max}}$, and mean rotation rate. The cumulative distribution function (hereafter CDF; e.g. Wall & Jenkins 2012) of the EVPA swings $\Delta \theta_{\text{max}}$ and rotation rates for blazars in the main sample which showed rotations (‘rotators’), blazars in the main sample, which did not show rotations (‘non-rotators’), as well as for blazars in the control sample, are shown in Fig. 4.

We performed a two sample Kolmogorov–Smirnov (K–S) test (e.g. Wall & Jenkins 2012) pairwise for three samples of collected swing amplitudes and rates with the null-hypothesis that these samples are drawn from the same distribution. The null-hypothesis is rejected for rotators and non-rotators with the $p$-value $= 1.2 \times 10^{-5}$, and for rotators and the control sample ($p$-value $= 5 \times 10^{-3}$). At the same time the distribution of swing amplitudes in the non-rotators and control sample sources is indistinguishable according to the test ($p$-value $= 0.35$). The maximum difference between the CDFs of non-rotators and rotators is 0.29. It is reached at $\Delta \theta_{\text{max}} \approx 25^\circ$. Even if we exclude the 14 rotations (i.e. the largest $\Delta \theta_{\text{max}}$ swings) of the main sample blazars, rotators still remain different from the non-rotators ($p$-value $= 2 \times 10^{-3}$).

A similar analysis (as the one for $\Delta \theta_{\text{max}}$) for the distributions of EVPA swing rates leads to the same conclusion. The
null-hypothesis is rejected for the rotators and the non-rotators ($p$ - value $= 1.4 \times 10^{-6}$) and rotators versus the control sample ($p$ - value $= 5 \times 10^{-3}$), while it cannot be rejected for the non-rotators and control sample ($p$ - value $= 0.18$).

We therefore conclude that blazars with detected rotations show significantly larger $\Delta \theta_{\max}$ and faster EVPA variations when compared to blazars with no detected rotations. This difference cannot be attributed to differences in the sampling properties of the data sets. Therefore, the lack of detection of EVPA rotations in the 'non-rotators' member of the main sample, as well as the blazar in the control sample, may have a physical origin. Most of the non-rotators in the main and control samples may never show an EVPA rotation.

4 RANDOM WALKS AS THE ORIGIN OF EVPA ROTATIONS

4.1 MC simulations of EVPA swings

Potentially EVPA swings can be explained by a stochastic process, which is physically justified by a presence of many independent cells in the emission region (e.g. Jones et al. 1985; D’Arcangelo et al. 2007). According to this interpretation, the magnetic field is turbulent and apparent rotations result from a random walk of the full polarization vector direction as new cells with random magnetic field orientations appear in the emission region (Marscher 2014). In order to estimate the probabilities that the EVPA rotations we observed with RoboPol are produced by this kind of multicell random walk process we performed MC simulations of the stochastic variability of the polarization vector on the QU plane following Kiehlmann et al. (2013).

For each blazar where an EVPA rotation event was observed, we created $10^5$ artificial light curves, each one with duration $T_{\text{obs}}$. The time steps $\Delta t_i$ between consecutive points were drawn from a truncated power-law distribution, which approximates well the distribution of the time steps in all observed light curves. The parameters of this distribution ($\Delta t_{\text{min}}, \Delta t_{\text{max}}$ and the power-law index) were determined by fitting it to the distribution of observed $\Delta t_i$ for each object.

The total flux density $I_i$ emitted at each time step $\Delta t_i$, was drawn from a lognormal distribution. Such a distribution approximates reasonably well the distribution of the observed flux densities for all blazars. The mean and variance of the lognormal distribution was set equal to the sample mean and variance of the distribution of the flux density of each blazar.

The maximum possible fractional polarization produced by a uniform magnetic field is $P_{\text{max}} = (\alpha + 1)/(\alpha + 5/3) \approx 0.78$ (Pacholczyk 1970). In the case of unresolved emission region comprising $N$ independent cells with a uniform magnetic field, but randomly oriented among them, the average fractional polarization is given by the equation (Hughes & Miller 1991):

$$\langle P_{\text{obs}} \rangle \approx P_{\text{max}} \frac{1}{\sqrt{N}}.$$  

We used this equation and the observed average polarization fraction, $\langle P_{\text{obs}} \rangle$, to estimate the number of cells, $N$, for each blazar. Each $k$th cell at $i$th time step was assigned a flux density $I_{i,k}$ (which was set equal to $I_i/N$ for all cells at each time step) and a set of fractional Stokes parameters $q_{i,k}$ and $u_{i,k}$. They were found as

$$q_{i,k} = q_{0,k} \frac{P_{\text{obs}}}{\sqrt{q_{0,k}^2 + u_{0,k}^2}},$$

$$u_{i,k} = u_{0,k} \frac{P_{\text{obs}}}{\sqrt{q_{0,k}^2 + u_{0,k}^2}},$$

where $q_{0,k}$ and $u_{0,k}$ are two numbers drawn from the standard normal distribution. Thereby the emission of each cell has polarization fraction $P_{\text{max}}$. The sums $Q_i = I_i \sum_{k=1}^{N} q_{i,k}$ and $U_i = I_i \sum_{k=1}^{N} u_{i,k}$ determine the total Stokes parameters of the emitting region at each time step.

At each time step the Stokes parameters of $N_{\text{rot}}(\Delta t_i)$ cells, selected randomly, were replaced by new values. The number of cells for replacement was estimated (from the average variance of the polarization degree) as follows:

$$N_{\text{rot}}(\Delta t_i) = \frac{\sigma(P_{\text{obs}})}{\langle \Delta t_i \rangle} \langle P_{\text{obs}} \rangle N,$$

where $\sigma(P_{\text{obs}})$ is the observed standard deviation of the degree of polarization for each blazar, and $\langle \Delta t_i \rangle$ is the average time difference between observations.

It was confirmed that the simulated and observational data in corresponding blazars have similar statistical properties. Namely, the standard deviation and average of the polarization fraction are consistent with $\sigma(P_{\text{obs}})$ and $\langle P_{\text{obs}} \rangle$.

4.1.1 Individual rotations

Using the algorithm described in Section 3, i.e. the same algorithm we used to identify rotations in real data, we identified all rotations in the simulated data and found the number $N_{\text{rot}}$ of ‘successful’ data sets, where at least one rotation with $\Delta \theta_{\text{max}}$ larger or equal to $\Delta \theta_{\text{max,obs}}$ was detected. We then estimated two ratios: $P(\text{RW}) = N_{\text{rot}}/10^4$ and $T_{\text{sec}} = 10^4 T_{\text{obs}}/N_{\text{rot}}$. The first ratio determines the probability to observe an EVPA rotation due to a random walk for each one of the observed EVPA curves for the given $T_{\text{obs}}$. The second ratio determines the average time interval between random walk rotations (i.e. the average occurrence rate for each blazar). The probabilities $P(\text{RW})$ and $T_{\text{sec}}$ are listed in Table 5. The probabilities are larger than 10 per cent in all but one object, and in some cases, they approach unity. This result indicates that the rotations we observed in some objects could be the result of a random walk process.

4.1.2 Rotations as a population

In this section, we test the hypothesis that all the rotations observed by RoboPol in blazars of the main sample are produced by the stochastic process. According to the analysis in Section 3.4 blazars exhibiting rotations have different properties when compared to non-rotators. Therefore, the sample of rotators must be considered separately.
In order to quantify a possible connection between EVPA rotations and gamma-ray activity, we first compared the average gamma-ray photon fluxes for each blazar during rotation events with the rest of the RoboPol season where no rotation was detected. Fig. 6 shows the gamma-ray light curves of blazars with detected rotations of EVPA. The green (light) area indicates the first year RoboPol observational season for each object and the pink (dark) area indicates the period of the detected rotation. The average photon fluxes (listed in Table 6) were calculated using the time intervals corresponding to the rotating and non-rotating periods as single time bins (or averaging fluxes for two/three non-rotating time bins in cases, where they are split by the rotations). The gamma-ray photon flux during a rotation was higher than the flux during the rest of the season at 1σ level only in four cases. The average difference between the photon flux during rotations and along the rest of the season is $-0.3 \pm 3.4 \times 10^{-9}$ ph cm$^{-2}$ s$^{-1}$. Thus, we do not observe any significant systematic change of the average gamma-ray photon flux simultaneous with the EVPA rotations.

However, a comparison of the mean flux levels during the rotation and over a relatively long period may not be the best way to search for a correlation between the gamma-ray activity and EVPA rotations. For instance, in the cases of RBPLJ0721+7120 and first rotation of RBPLJ2232+1143, rotations are clearly coincident with prominent flares, although the average gamma-ray photon fluxes are indistinguishable, since the season comprises a number of flaring events with similar amplitude. Moreover, rotations of EVPA can either precede or follow gamma-ray flares according to various theoretical scenarios. It is therefore important to search for a possible correlation between EVPA rotations and gamma-ray flares.

### 5.2 Time lags between flares and EVPA rotations

In order to investigate this relation, we first identified all flares that happened in the gamma-ray light curves during the RoboPol observing season.

We adopted a formal definition of a gamma-ray flare similar to the one proposed by Nalewajko (2013): ‘a flare is a contiguous period of time, associated with a given photon flux peak, during which the photon flux exceeds half of the peak value, and this lower limit is attained exactly twice – at the start and at the end of the flare’. However, the definition was slightly changed because Nalewajko (2013) analysed a sample of the brightest flares ever detected by Fermi LAT, while we are interested in even smaller amplitude events. We found that a peak photon flux excess factor equal to 2/3, instead of the original 1/2 proposed by Nalewajko (2013), gives a better agreement with a visual identification of flares in the photon flux curves. Intervals of the photon flux curves identified as flares are marked by red (light) points in Fig. 6.

We searched for the closest gamma-ray flare to the rotation event of each rotator, and we fitted it using a profile with an exponential rise and decay. This kind of profile is commonly used for fitting an...
Figure 6. Gamma-ray light curves of objects with detected rotations of EVPA. The RoboPol observational season is marked by the green (light) area. The pink (dark) area shows duration of the rotation. Green ticks mark moments of our optical EVPA measurements. All curves are centred to the mean day of the RoboPol observing season. Detected flares are marked by red points, while the blue curve is the analytical function fit of the flares closest to observed rotations (see text for details). Vertical dashed lines indicate intervals of the light curves used in the fitting procedure.
individual blazar flare pulse in optical, gamma and radio bands (e.g. Abdo et al. 2010b; Chatterjee et al. 2012):

$$F(t) = F_c + F_p \left( e^{-t/T_\text{rise}} + e^{-t/T_\text{fall}} \right)^{-1},$$

(4)

where $F_c$ represents an assumed constant level underlying the flare, $F_p$ measures the amplitude of the flare, $t_p$ describes the time of the peak (it corresponds to the actual maximum only for symmetric flares), $T_\text{rise}$ and $T_\text{fall}$ measure the rise and decay time, respectively. All the parameters were set to be free, while initial values used in the fitting procedure were estimated from the photon flux curves. Upper limits of the light curve were not used in the fitting procedure. In the case of RBPLJ0721+7120 three flares that occurred during the observing season were fitted simultaneously because a single flare fit resulted in an unrealistic $F_c$ value. In the cases of double rotations in RBPLJ1806+6949 and RBPLJ2232+1143 the flares closest to the rotations were also fitted together to provide a consistent $F_c$ value. In addition, in three cases, the closest flares happened just outside the RoboPol season interval. The best-fitting curves are shown in Fig. 6.

We estimated time lags, $\tau_{\text{obs}}$, between rotations and the closest gamma-ray flares as $\tau_{\text{obs}} = \bar{T}_\text{rot} - t_p$, where $\bar{T}_\text{rot}$ is the middle point of each EVPA rotation, defined as $t_{\text{rot, start}} + \frac{T_\text{rot}}{2}$ (see Table 7).

The time lags have a distribution, shown by green (light) bars in Fig. 6, with mean and standard deviation equal to 5.1 and 21.8 d, respectively. The distribution is indistinguishable from the normal distribution $N(0, 21.8)$ following the K–S test ($p$-value = 0.39). Thereby we do not find any preference for positive or negative $\tau_{\text{obs}}$. A distribution of observed time lags is expected to be close to a normal distribution with the mean at zero if rotations of the EVPA are not connected to gamma-ray flares. Because, in this case, the overall distribution is produced by a set of random values each having distributions of different widths and symmetric with respect to zero. For this reason the time lags distribution does not, on its own, support a physical connection between gamma-ray flares and rotations. However, theoretical models allow for either positive or negative lags, depending on conditions and emission region properties, when a physical connection between rotations and gamma-ray flares does exist (Zhang, Chen & Böttcher 2014). Therefore, a physical connection cannot be excluded based on the distribution of $\tau_{\text{obs}}$.

5.3 Relation of gamma-ray flare amplitudes and time delays

We normalized the amplitude, $F_p$, of the gamma-ray flare closest to the EVPA rotation event by the average photon flux of each blazar (as listed in 2FGL; Nolan et al. 2012). Corresponding values are listed in Table 7 and plotted as a function of $\tau_{\text{obs}}$ in Fig. 8. The filled black squares show redshift-corrected time lags, i.e. $\tau_{\text{corr}} = \tau_{\text{obs}}/(1 + z)$, while open circles show $\tau_{\text{obs}}$ for blazars with unknown $z$. The ‘errors’ on the time lags are defined as fitting errors of $t_p$ plus the time difference between the first/last point of a rotation event, and the previous/next closest point of the EVPA curve. Due to the lack of data in some cases these ‘uncertainties’ are undefined, while in others, due to sparse sampling, they are almost certainly overestimated.

A noticeable feature is that $\tau_{\text{corr}}$ is in the range $(-6, +6)$ d for the most prominent gamma-ray flares. Basically, all five brightest flares have happened almost simultaneously with EVPA rotation...
Repeating this simulation 10⁴ times for each blazar, we determined between the rotation and the closest gamma-ray flare, that we randomly assigned the middle point of a simulated rotation to the photon flux curves of rotators is in the range of 12–76. After flares following the procedure described previously, using the same used in Section 5.2. Then we identified and fitted all gamma-ray flares. (1) – blazar identifier; (2) probability of an accidental time lag; (3) – combined probability of a rotation being produced by the random walk and located as close to the corresponding gamma-ray flare as it was observed.

There are three more flares with similarly small time lags, and small relative amplitudes. Thus, a small separation between a flare and a rotation is not a sufficient condition for extraordinary brightness of the high-energy flare.

Separating the flares into two subsamples of high and low amplitude events (dashed line in Fig. 8) we examined the significance of the difference in time delays between them. The mean of the absolute \( \tau_{\text{obs}} \) values for the high and low amplitude subsamples is 5.2 and 20.1 d, respectively. According to the Student’s \( t \)-test (e.g. Wall & Jenkins 2012), the difference between the two mean values is somewhat significant (\( p - \text{value} = 0.025 \)).

5.4 Accidental proximity of rotations and gamma-ray flares

5.4.1 Individual blazars

In order to estimate the probability of the accidental observed proximity in time of rotations and gamma-ray flares, we performed MC simulations using the observed gamma-ray photon flux curves. This allows us to account for the real variability of blazars in the gamma-ray band. For each rotator we processed a long-term set of LAT data (54683 ≤ MJD ≤ 57065) with time bins equal to the ones used in Section 5.2. Then we identified and fitted all gamma-ray flares following the procedure described previously, using the same photon flux excess factor of 1.5. The number of flares identified in the photon flux curves of rotators is in the range of 12–76. After that we randomly assigned the middle point of a simulated rotation to a time on the photon flux curve and measured the time lag between the rotation and the closest gamma-ray flare, \( \tau_{\text{simul}} \). Repeating this simulation 10⁴ times for each blazar, we determined the distributions of time delays \( \tau_{\text{simul}} \). Using these distributions, we estimated the probability of \( \tau_{\text{obs}} \) to be produced by chance \( P(\tau_{\text{obs}}) \), by calculating the fraction of simulations where \( \tau_{\text{simul}} \leq \tau_{\text{obs}} \). The probabilities range between 3 and 78 per cent (see Table 8).

Figure 8. Time lags, \( \tau_{\text{obs}} \), versus normalized gamma-ray flare amplitude, \( F_{\gamma} \). Redshift corrected and non-corrected \( \tau_{\text{obs}} \) values are plotted with filled squares and open circles, respectively.

distributions cannot be rejected (\( p - \text{value} = 0.38 \)). Therefore, it is possible that the \( \tau_{\text{obs}} \) values we observed, may be accidental for each of the blazars in the sample.

In Section 4.1, we determined the probability of the EVPA rotations to be observed in our observing window assuming that they are produced by a stochastic process. The simulations described above give us the probability of an accidental simultaneity between these rotations and gamma-flares. Therefore, the probability of superposition of both independent events: (a) random rotation and (b) random proximity to a gamma-ray flare, can be estimated as a product of the respective probabilities. These combined probabilities are less than 5 per cent for five events (see column 3 of Table 8). This result indicates that, at least for some rotations, the random walk model and the absence of any physical connection between the EVPA variability and high-energy activity is an unfavourable interpretation.

5.4.2 Rotators as a population

In order to assess the probability that the entire set of the time lags appeared in the main sample rotators in a random way, we run the following simulation. Repeating the procedure described in Section 5.2, we identified and fitted all flares in the gamma-ray band data (54683 ≤ MJD ≤ 57065) of each blazar from the main sample with a detected rotation. Then placing a simulated rotation at a random position on each of the gamma-ray curves, we defined the shortest time lag between the central point of the rotation and \( t_{\gamma} \) of the nearest flare. After this the CDF of absolute values of the simulated time lags was constructed for the set of 14 events.

Repeating the routine 10⁶ times we found that only one out of every 5000 simulations produces a CDF which is in its entirety located closer to zero or coincides with the CDF of observed time lags (see Fig. 9). Thereby we estimate the probability that all 14 delays together were produced by chance as \( 2 \times 10^{-4} \). When we repeat this procedure for all 16 rotations together including two non-main sample events, the estimated probability decreases to \( 5 \times 10^{-5} \).
Therefore, it is very unlikely that none of the observed EVPA rotations is related physically to the flaring activity in gamma-rays.

6 CONCLUSIONS

During the first season of operation of the RoboPol project, we detected 16 rotations of the polarization plane in optical emission of blazars. These detections double the existing list of such events. All EVPA rotations are observed in blazars which are detected by Fermi, in agreement with previous experiments, which have detected similar events in the same class of objects. Our strategy of monitoring both gamma-ray–loud and quiet samples, suggests that the lack of EVPA rotations detection by RoboPol in gamma-ray–quiet objects cannot be due to a difference in the sampling pattern. Combining our results with those reported in the literature we found that rotations can be detected in both TeV and non-TeV emitters. Our results also indicate that all subcategories of blazars show rotations of the EVPA (regardless of the position of the synchrotron peak maximum or the BL Lac/FSRQ dichotomy). We expect that the results after the 3-yr planned RoboPol monitoring campaign will allow an accurate determination of the rotations rate in the various blazar subclasses.

Analysis of the first-year data shows that blazars with detected rotations have significantly faster and longer EVPA swings when compared to non-rotators. This suggests that rotations of EVPA may be specific for a particular activity state or for a subclass of blazars with peculiar properties.

The fact that EVPA rotations have been detected only in gamma-ray–loud objects already suggests a physical relation between gamma-ray and optical polarization variability in blazars. Nevertheless, we used extensive MC simulations to investigate whether the EVPA rotations we observed can be produced by a random walk process of the polarization vector. We found that a random walk process can result in EVPA rotations with $\Delta \theta_{\text{max, simul}}$ as large as $\Delta \theta_{\text{max, obs}}$ for the given $\Delta t$-median and $T_{\text{obs}}$ of the individual RoboPol data sets. However, we also found that it is unlikely (probability is $\leq 1.5 \times 10^{-2}$) that all the rotations that we observed in the first RoboPol season are due to a random walk process.

The average gamma-ray photon fluxes do not show any significant systematic increase during the rotation events. We also found that, the time lags between rotations of the EVPA and nearest gamma-ray flares follow a Gaussian distribution with a mean $\approx 0$.

We performed a second set of MC simulations in order to assess the randomness of the observed time delays. Our results suggest that, on an individual basis, the time lags we observe do not necessarily suggest a physical link between EVPA rotations and gamma-ray flares. On the other hand, when we consider the rotators as a population, it is highly unlikely ($p = 2 \times 10^{-4}$) that the proximity of EVPA rotations to gamma-ray flares is accidental in all cases. Therefore, at least some EVPA rotations must be physically connected to the high-energy activity.

Our data suggest that, the highest amplitude gamma-ray flares may be physically connected with EVPA rotations, based on the fact that they are associated with smaller-than-average time lags. Perhaps there are two different types of gamma-ray flares, produced by different physical mechanisms. One of them may result in higher (than average) amplitude flares and EVPA rotation events. The other one may produce the rest of the smaller amplitude flares, which are not related with the remaining rotations, probably produced by a random walk process.

For the first time we studied a set of EVPA rotations discovered in a large, well-defined, regularly monitored sample of blazars. The diversity of results found in individual and population analysis shows the importance of these kinds of studies. The RoboPol monitoring of blazars will continue for at least two more years. The question about the mechanisms responsible for the EVPA rotations in blazars and their possible connection to the high-energy activity will be explored in more detail after accumulation of a larger data set by RoboPol.

The statistical analysis of our data set required us to make subjective choices regarding the details of our event definitions and the test statistics we used. These, for example, include the definition of a rotation, the definition of a ‘gamma-ray activity’ (increase in gamma-ray flux during a rotation versus proximity to a gamma-ray flare peak), the definition and fitting procedure of a gamma-ray flare, use of the $\Delta \theta_{\text{max}}$ and $|\tau_{\text{obs}}|$ CDFs as test statistics and so forth. Making these choices introduces unavoidable and unquantifiable biases in our final results. However, our exploratory analysis of the first-year data presented here has allowed us to identify well-defined statistical questions, which we can address in a robust, a priori fashion using our second- and third-year data.

ACKNOWLEDGEMENTS

The RoboPol project is a collaboration between Caltech in the USA, MPIfR in Germany, Toruń Centre for Astronomy in Poland, the University of Crete/FORTH in Greece and IUCAA in India. The University of Crete group acknowledges support by the ‘RoboPol’ project, which is implemented under the ‘Aristeia’ Action of the ‘Operational Programme Education and Lifelong Learning’ and is co-funded by the European Social Fund (ESF) and Greek National Resources, and by the European Commission Seventh Framework Programme (FP7) through grants PIGCIG10-2011-304001 ‘Jet-Pop’ and PIRSES-GA-2012-31578 ‘EuroCal’. This research was supported in part by NASA grant NNX11A043G and NSF grant AST-1109911, and by the Polish National Science Centre, grant number 2011/01/B/ST9/04618. KT acknowledges support by the FP7 through the Marie Curie Career Integration Grant PCIG-GA-2011-293531 ‘SFOnset’. MB acknowledges support from NASA Headquarters under the NASA Earth and Space Science Fellowship Program, grant NNX14AQ07H. TH was supported in part by the Academy of Finland project number 267324. IM and SK are...
supported for this research through a stipend from the International Max Planck Research School (IMPRS) for Astronomy and Astrophysics at the Universities of Bonn and Cologne. The Fermi LAT Collaboration acknowledges generous ongoing support from a number of agencies and institutes that have supported both the development and the operation of the LAT as well as scientific data analysis. These include the National Aeronautics and Space Administration and the Department of Energy in the United States, the Commissariat à l’Énergie Atomique and the Centre National de la Recherche Scientifique/Institut National de Physique Nucléaire et de Physique des Particules in France, the Agenzia Spaziale Italiana and the Istituto Nazionale di Fisica Nucleare in Italy, the Ministry of Education, Culture, Sports, Science and Technology (MEXT), High Energy Accelerator Research Organization (KEK) and Japan Aerospace Exploration Agency (JAXA) in Japan, and the K. A. Wallenberg Foundation, the Swedish Research Council and the Swedish National Space Board in Sweden, Istituto Nazionale di Astrofisica in Italy and the Centre National d’Études Spatiales in France.
